A B S T R A C T

Background: The World Health Organization (WHO) and the International Labour Organization (ILO) are developing the WHO/ILO Joint Estimates of the Work-related Burden of Disease and Injury (WHO/ILO Joint Estimates), supported by a large number of individual experts. Evidence from previous reviews suggests that exposure to long working hours may cause depression. In this article, we present a systematic review and meta-analysis of parameters for estimating (if feasible) the number of deaths and disability-adjusted life years from depression that are attributable to exposure to long working hours, for the development of the WHO/ILO Joint Estimates.
Objectives: We aimed to systematically review and meta-analyse estimates of the effect of exposure to long working hours (three categories: 41–48, 49–54 and ≥55 h/week), compared with exposure to standard working hours (35–40 h/week), on depression (three outcomes: prevalence, incidence and mortality).
Data sources: We developed and published a protocol, applying the Navigation Guide as an organizing systematic review framework where feasible. We searched electronic academic databases for potentially relevant records from published and unpublished studies, including the WHO International Clinical Trial Registers Platform, Medline, PubMed, EMBASE, Web of Science, CISDOC and PsycInfo. We also searched grey literature databases, Internet search engines and organizational websites; hand-searched reference lists of previous systematic reviews; and consulted additional experts.
Study eligibility and criteria: We included working-age (≥15 years) workers in the formal and informal economy in any WHO and/or ILO Member State but excluded children (aged <15 years) and unpaid domestic workers. We included randomized controlled trials, cohort studies, case-control studies and other non-randomized intervention studies with an estimate of the effect of exposure to long working hours (41–48, 49–54 and ≥55 h/week), compared with exposure to standard working hours (35–40 h/week), on depression (prevalence, incidence and/or mortality).
Study appraisal and synthesis methods: At least two review authors independently screened titles and abstracts against the eligibility criteria at a first stage and full texts of potentially eligible records at a second stage, followed by extraction of data from qualifying studies. Missing data were requested from principal study authors. We combined odds ratios using random-effects meta-analysis. Two or more review authors assessed the risk of bias, quality of evidence and strength of evidence, using Navigation Guide and GRADE tools and approaches adapted to this project.
Results: Twenty-two studies (all cohort studies) met the inclusion criteria, comprising a total of 109,906 participants (51,324 females) in 32 countries (as one study included multiple countries) in three WHO regions (Americas, Europe and Western Pacific). The exposure was measured using self-reports in all studies, and the outcome was assessed with a clinical diagnostic interview (four studies), interview questions about diagnosis and treatment of depression (three studies) or a validated self-administered rating scale (15 studies). The outcome was defined as incident depression in all 22 studies, with first time incident depression in 21 studies and recurrence of depression in one study. We did not identify any study on prevalence of depression or on mortality from depression. For the body of evidence for the outcome incident depression, we had serious concerns for risk of bias due to selection because of incomplete outcome data (most studies assessed depression only twice, at baseline and at a later follow-up measurement, and likely have missed cases of depression that occurred after baseline but were in remission at the time of the follow-up measurement) and due to missing information on life-time prevalence of depression before baseline measurement.
Compared with working 35–40 h/week, we are uncertain about the effect on acquiring (or incidence of) depression of working 41–48 h/week (pooled odds ratio (OR) 1.05, 95% confidence interval (CI) 0.86 to 1.29, 8 studies, 49,392 participants, I^2 46%, low quality of evidence); 49–54 h/week (OR 1.06, 95% CI 0.93 to 1.21, 8 studies, 49,392 participants, I^2 40%, low quality of evidence); and ≥ 55 h/week (OR 1.08, 95% CI 0.94 to 1.24, 17 studies, 91,142 participants, I^2 46%, low quality of evidence).
Subgroup analyses found no evidence for statistically significant ($P < 0.05$) differences by WHO region, sex, age group and socioeconomic status. Sensitivity analyses found no statistically significant differences by outcome measurement (clinical diagnostic interview [gold standard] versus other measures) and risk of bias ("high"/"probably high" ratings in any domain versus "low"/"probably low" in all domains).
Conclusions: We judged the existing bodies of evidence from human data as "inadequate evidence for harmfulness" for all three exposure categories, 41–48, 48–54 and ≥55 h/week, for depression prevalence, incidence and mortality; the available evidence is insufficient to assess effects of the exposure. Producing estimates of the burden of depression attributable to exposure to long working appears not evidence-based at this point. Instead, studies examining the association between long working hours and risk of depression are needed that address the limitations of the current evidence.

1. Background

`The World Health Organization (WHO) and the International Labour Organization (ILO) are producing the WHO/ILO Joint Estimates of the Work-related Burden of Disease and Injury (WHO/ILO Joint Estimates) (Ryder, 2017). The organizations are estimating the numbers of deaths and disability-adjusted life years (DALYs) that are attributable to selected occupational risk factors. The WHO/ILO Joint Estimates are based on already existing WHO and ILO methodologies for estimating the burden of disease for selected occupational risk factors (Ezzati et al., 2004;

International Labour Organization, 1999, 2014; Prüss-Üstün et al., 2017). They expand these existing methodologies with estimation of the burden of several prioritized additional pairs of occupational risk factors and health outcomes. For this purpose, population attributable fractions (Murray et al., 2004) – the proportional reduction in burden from the health outcome achieved by a reduction of exposure to the risk factor to zero – are being calculated for each additional risk factor-outcome pair, and these fractions are being applied to the total disease burden envelopes for the health outcome from the WHO Global Health Estimates for the years 2000–2016 (World Health Organization, 2019).

The WHO/ILO Joint Estimates may include estimates of the burden of depression attributable to exposure to long working hours, if feasible, as one additional risk factor-outcome pair whose global burden of disease has not previously been estimated. To select parameters with the best and least biased evidence for our estimation models, we conducted a systematic review and meta-analysis of studies on the relationship between exposure to long working hours and depression according to our protocol (Rugulies et al., 2019), and we present its results in the current paper. A systematic review of studies estimating the prevalence of exposure to long working hours is ongoing (Sembajwe et al., forthcoming) and applies novel systematic review methods (Pega et al., 2020b). WHO and ILO have conducted or are conducting several other systematic reviews and meta-analyses on other additional risk factor-outcome pairs (Descatha et al., 2018; Descatha et al., 2020; Godderis et al., 2018; Hulshof et al., 2019; Hulshof et al., 2021a; Hulshof et al., 2021b; Li et al., 2018; Li et al., 2020; Mandrioli et al., 2018; Pachito et al., 2020; Paulo et al., 2019; Pega et al., 2020a; Teixeira et al., 2021a; Teixeira et al., 2019; Teixeira et al., 2021b; Tenkate et al., 2019). To our knowledge, these are the first systematic reviews and meta-analyses (with a pre-published protocol) conducted specifically for an occupational burden of disease study. An editorial provides an overview of this series of systemic reviews and meta-analyses from the WHO/ILO Joint Estimates and outlines its scientific, methodological, policy, editorial and other innovations (Pega et al., 2021a). The WHO/ILO joint estimation methodology and the WHO/ILO Joint Estimates are separate from these systematic reviews, and they are described in more detail and reported elsewhere. WHO/ILO Joint Estimates have just been published of the global, regional and national burdens of ischemic heart disease and stroke attributable to exposure to long working hours for 194 countries for the years 2000, 2010 and 2016 (Pega et al., 2021b).

1.1. Rationale

To consider the feasibility of estimating the burden of depression attributable to exposure to long working hours, and to ensure that potential estimates of burden of depression are reported in adherence with the *Guidelines for Accurate and Transparent Health Estimates Reporting* (GATHER) (Stevens et al., 2016), WHO and ILO require a systematic review of studies on the prevalence of relevant levels of exposure to long working hours (Sembajwe et al., forthcoming), as well as a systematic review and meta-analysis with estimates of the relative effect of exposure to long work hours on depression prevalence, incidence and mortality, compared with the theoretical minimum risk exposure level (the systematic review presented here). The theoretical minimum risk exposure level is the exposure level that would result in the lowest possible population risk, even if it is not feasible to attain this exposure level in practice (Murray et al., 2004). These data and effect estimates should be tailored to serve as parameters for estimating the burden of depression from exposure to long work hours in the WHO/ILO Joint Estimates.

We are aware of at least three prior systematic reviews on the effect of long working hours on depression published since 2015. First, Theorell et al., reported, based on six cohort studies of high or moderate quality, that there was a prospective association of long working hours (denoted as "long working weeks" by the authors) with risk of onset of depressive symptoms (Theorell et al., 2015). Using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach (Morgan et al., 2016), they assessed the evidence as "limited" for women and "very limited" for men. The authors refrained from upgrading the evidence level for long working hours, because they found the estimates of the association between long working hours and depression neither consistent, nor large enough, for qualifying for an upgrade; they also did not conduct a meta-analysis of the included effect estimates. Second, Watanabe et al., examined overtime work and risk of onset of depressive disorders and identified seven cohort studies (Watanabe et al., 2016). The meta-analysis conducted in this systematic

review showed an increased, but not statistically significant, association between working ≥50 h/week and risk of depressive disorders (relative risk (RR) 1.24, 95% CI 0.88 to 1.75). Third, Virtanen et al., included in their meta-analysis ten published cohort studies and 18 unpublished cohort studies with individual-participant data, yielding 31 study-specific estimates (as three studies of the published studies had provided estimates stratified by sex) (Virtanen et al., 2018). The outcome was named "depressive symptoms" and included both measures of clinical depression and depressive symptoms and of psychological distress. The overall pooled estimate for the association of long working hours with risk of onset of "depressive symptoms" was an odds ratio (OR) of 1.14 (95% CI 1.03 to 1.25). The association was stronger in studies from Asian countries (OR 1.50, 95% CI 1.13 to 2.01), weaker in European studies (OR 1.11, 95% CI 1.00 to 1.22), and absent in North American studies (OR 0.95, 95% CI 0.70 to 1.29) and in the one study from the Western Pacific (Australia only) (OR 0.95, 95% CI 0.70 to 1.29). When stratified by "depression" (including clinical depression and depressive symptoms) versus psychological distress, the pooled ORs were 1.09 (0.94 to 1.26) and 1.18 (1.06 to 1.32) for clinical depression/depressive symptoms and psychological distress, respectively. Meta-regressions did not show any statistically significant (P = 0.05) differences in the estimates for clinical depression, depressive symptoms and psychological distress. In summary, the previous systematic review and meta-analytic evidence appears to be inconclusive with regards to the outcome of depression. To our knowledge, prior systematic reviews did not have a pre-published protocol and/or missed other essential aspects of a systematic review. Our systematic review is fully compliant with latest systematic review methods (including use of a pre-published protocol: Rugulies et al., 2019) and expands the scope of the existing systematic review evidence by covering evidence from studies published up to 28 November 2019.

Our systematic review covers workers in the formal and in the informal economy. The informal economy is defined as "all economic activities by workers and economic units that are – in law or in practice – not covered or insufficiently covered by formal arrangements" (104th International Labour Conference 2015). It does not comprise "illicit activities, in particular the provision of services or the production, sale, possession or use of goods forbidden by law, including the illicit production and trafficking of drugs, the illicit manufacturing of and trafficking in firearms, trafficking in persons and money laundering, as defined in the relevant international treaties" (104th International, 2015). Work in the informal economy may lead to different exposures and exposure effects than work in the formal economy does. Consequently, formality of work (informal versus formal economy) may modify the effect of long working hours on depression. Therefore, we consider in the systematic review the formality of the economy reported in included studies.

1.2. Description of the risk factor

Burden of disease estimation requires unambiguous definition of the risk factor, risk factor levels and the theoretical minimum risk exposure level. Long working hours are defined as working hours exceeding standard working hours, i.e. any working hours of >40 h/week (Table 1). Based on results from earlier studies on long working hours and health endpoints (Kivimäki et al., 2015; Virtanen et al., 2015), the preferred four exposure level categories for our systematic review are 35–40, 41–48, 49–54 and ≥55 h/week (Table 1).

The theoretical minimum risk exposure is standard working hours defined as 35–40 h/week (Table 1). We acknowledge that it is possible that the theoretical minimum risk exposure might be lower than standard working hours, but we have to exclude working hours < 35 h/week, because studies indicate that some persons working less than standard hours do so because of existing health problems or family care obligations (Kivimäki et al., 2015; Sokejima and Kagamimori, 1998). In other words, persons working less than standard hours might belong to a

Table 1
Definitions of the risk factor, risk factor levels and the minimum risk exposure level.

	Definition
Risk factor	Exposure to long working hours (including those spent in secondary jobs), defined as working hours >40 h/week, i.e. working hours exceeding standard working hours (35–40 h/week).
Risk factor levels	Four levels: 35–40 h/week. 41–48 h/week. 49–54 h/week. ≥55 h/week.
Theoretical minimum risk exposure level	Standard working hours, defined as working hours of 35–40 h/week.

Source: (Rugulies et al., 2019).

health-selected group or a group concerned with family care and therefore cannot serve as comparators. Consequently, if a study used as the reference group persons working less than standard hours or a combination of persons working standard hours and persons working less than standard hours, it was excluded from the systematic review and meta-analysis. The category 35–40 h/week is the reference group used in many large studies and in the most recent systematic review by Virtanen et al. (Virtanen et al., 2018).

1.3. Definition of the outcome

The WHO Global Health Estimates group outcomes into standard burden of disease categories (World Health Organization, 2017), based on standard codes from the *International Statistical Classification of Diseases and Related Health Problems 10th Revision* (ICD-10) (World Health Organization, 2015). The relevant WHO Global Health Estimates category for this systematic review is "II.E.1 Major depressive disorders" (World Health Organization, 2017). In line with the WHO Global Health Estimates, we define the health outcome covered in this systematic review as depression, defined as conditions with ICD-10 codes F32, F33 and F34.1 (Table 2). Table 2 presents for each disease or health problem included in the WHO Global Health Estimates category the inclusion in this systematic review, showing that this review covers all the relevant categories.

1.4. How the risk factor may impact the outcome

Fig. 1 presents the logic model for our systematic review of the causal relationship between exposure to long working hours and depression, taken from our protocol (Rugulies et al., 2019). This logic model is an a priori, process-orientated one (Rehfuess et al., 2018) that seeks to capture the complexity of the risk factor–outcome causal relationship (Anderson et al., 2011).

Based on knowledge of previous research on long working hours and depression, we assume that the effect of long working hours on risk of depression may be mediated via (a) disturbance of work/life balance; (b) exhaustion; (c) emotional distress; (d) health-related behaviors, such as lack of physical activity, high alcohol consumption and reduced sleeping hours; and (e) psycho-physiological changes, such as activation

Table 2
ICD-10 codes and disease and health problems covered by the WHO Global Health Estimates category "II.E.1 Major depressive disorders" and their inclusion in the systematic review.

ICD-10 code	Disease or health problem	Included in this review
F32	Depressive episode	Yes
F33	Recurrent depressive episode	Yes
F34.1	Dysthymia	Yes

Source: (Rugulies et al., 2019).

of the hypothalamic–pituitaryadrenal (HPA) axis, inflammation processes, circadian disruptions, and sleep impairment (Baglioni et al., 2011; Bannai and Tamakoshi, 2014; Bergs et al., 2018; Boden and Fergusson, 2011; Fujimura et al., 2014; Gold, 2015; Kronfeld-Schor and Einat, 2012; McEwen, 2004; 2012; Pariante and Lightman, 2008; Pittenger and Duman, 2008; Virtanen et al., 2009; Virtanen et al., 2015).

As possible confounders, we consider age, sex and socioeconomic position (also denoted as socioeconomic status, SES); we assume that these variables may impact both exposure to long working hours and risk of depression. It is well established that women and persons with low SES have a higher risk of depression than men and persons with high SES (Kessler et al., 2003; Lorant et al., 2003; Wittchen and Jacobi, 2005). With regard to age, some studies indicate that the 12-month prevalence of depression is modestly higher in young adulthood than in middle adulthood (Kessler et al., 2003; Wittchen and Jacobi, 2005), although birth cohort effects may also play a role, with a higher prevalence of depression in more recent birth cohorts (Kessler et al., 2003). Age, sex and SES may also be related to number of working hours, although the direction of these relationships may depend on other variables and contextual factors (Bannai et al., 2016; Larsen et al., 2017; Lee et al., 2016; O'Reilly and Rosato, 2013; Organisation for Economic Cooperation and Development (OECD) 2018; Wirtz et al., 2012); thus, it appears reasonable to regard these three variables as potential confounders for the association of exposure to long working hours with depression. We addressed this possible confounding by including only studies in the meta-analysis that had adjusted or stratified for age, sex and SES or had been based on study samples that were homogenous with regard to these criteria (e.g., included only men or only individuals from the same occupational group).

It is possible that age, sex and SES are not only confounders, but also effect modifiers for the association of long working hours and depression, and we consequently conducted meta-analyses stratified by age, sex and SES. We further considered as effect modifiers country, industrial sector, occupation and formality of the economy and also conducted meta-analyses stratified by these variables, if data allowed this.

Fig. 1 also considers the macro and meso-level contexts that may impact the prevalence of exposure to long working hours, the effect of long working hours exposure on depression, or both (Commission of Social Determinants on Health, 2008; Dahlgreen and Whitehead, 2006; Martikainen et al., 2002; Rugulies et al., 2004).

2. Objectives

To systematically review and meta-analyse evidence on the effect of exposure to long working hours (three categories: 41–48, 49–54 and ≥55 h/week) on depression prevalence, incidence and mortality among workers of working age, compared with the minimum risk exposure level (standard working hours: 35–40 h/week).

3. Methods

3.1. Developed protocol

We applied the Navigation Guide (Woodruff and Sutton, 2014) methodology for systematic reviews in environmental and occupational health as our guiding methodological framework wherever feasible. The guide applies established systematic review methods from clinical medicine, including standard Cochrane methods for systematic reviews of interventions, to the field of environmental and occupational health to ensure systematic and rigorous evidence synthesis on environmental and occupational risk factors that reduces bias and maximizes transparency (Woodruff and Sutton, 2014). The need for further methodological development and refinement of the relatively novel Navigation Guide has been acknowledged (Woodruff and Sutton, 2014). From the perspective of the Navigation Guide framework, all steps were conducted (i.e., steps 1–6 in Fig. 1 in Woodruff and Sutton, 2014) for the
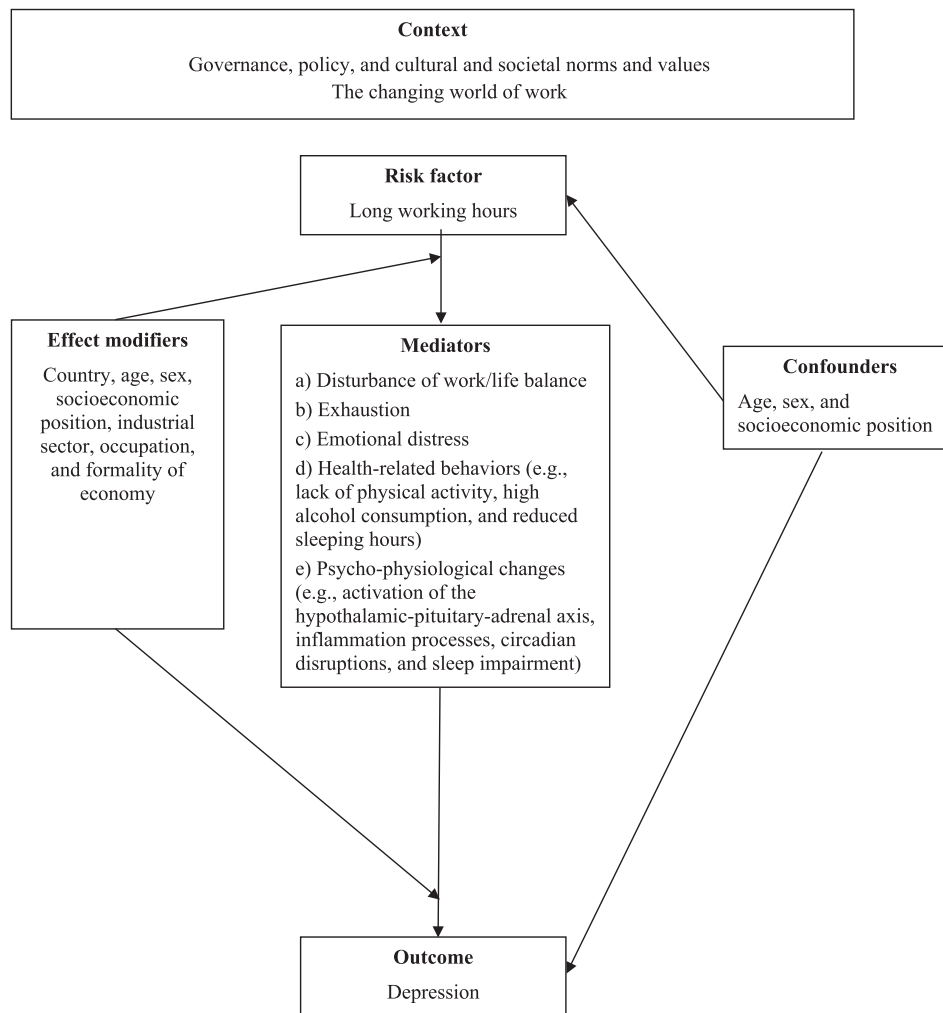

Fig. 1. Logic model of the possible causal relationship between exposure to long working hours and depression.

stream on human data and none of the steps for the stream on non-human data, although we narratively synthesized the mechanistic evidence from non-human data that we were aware of (Section 1.4).

We registered the protocol in PROSPERO under CRD42018085729. The protocol adheres to the preferred reporting items for systematic review and meta-analysis protocols statement (PRISMA-P) (Moher et al., 2015; Shamseer et al., 2015), with the abstract adhering to the reporting items for systematic reviews in journal and conference abstracts (PRISMA-A) (Beller et al., 2013). Any modification of the methods stated in the protocol was registered in PROSPERO and reported in the systematic review itself (Section 8). Our systematic review is reported according to the *Preferred Reporting Items for Systematic Reviews and Meta-Analyses Statement* (PRISMA) (Liberati et al., 2009). Our reporting of the parameters for estimating the burden of depression attributable to exposure to long working hours in the systematic review adheres with the requirements of the GATHER guidelines (Stevens et al., 2016), because the WHO/ILO Joint Estimates that may be produced consecutive to the systematic review must also adhere to these reporting guidelines.

3.2. Searched literature

3.2.1. Electronic academic databases
We searched the seven following electronic academic databases:
1. WHO International Clinical Trials Registry Platform (to 18 July 2018).
2. Ovid MEDLINE with Daily Update (1 January 1946 to 11 July 2018).
3. PubMed (1 January 1946 to 11 July 2018).
4. EMBASE (1 January 1947 to 11 July 2018).
5. Web of Science (1 January 1945 to 11 July 2018).
6. CISDOC archived database (1 January 1901 to 17 July 2018).
7. PsycINFO (1 January 1880 to 12 July 2018).

The Ovid MEDLINE search strategy was presented in the protocol (Rugulies et al., 2019). The full search strategies for all databases were revised by a research librarian and are presented in Appendix 1 in the Supplementary data. We performed searches in electronic databases operated in the English language using a search strategy in the English language. When we neared completion of the review, we conducted a top-up search of the MEDLINE database on 28 November 2019 to capture the most recent publications (e.g., publications ahead of print). Deviations from the proposed search strategy and the actual search strategy are documented in Section 8.

3.2.2. Electronic grey literature databases
We also searched the two following grey literature databases.

- OpenGrey (http://www.opengrey.eu/) (up to 25 July 2018)

- Grey Literature Report (http://greylit.org/) (searched on 5 August 2018 but last update of Grey Literature Report database was in January 2017)

The full search strategies for the two grey literature databases are presented in Appendix 1 in the Supplementary data.

3.2.3. Internet search engines

We also searched the Google (www.google.com/) and Google Scholar (www.google.com/scholar/) Internet search engines on 8 October 2018 using the search terms "work*" AND (depression OR depressive OR antidepressant). We screened the first 100 hits for potentially relevant records, as was previously done in Cochrane Reviews (Pega et al., 2015; Pega et al., 2017).

3.2.4. Organizational websites

The websites of the six following international organizations and national government departments were searched between September and November 2018 using the keywords "Behavioural symptoms", "Affective symptoms", "Mood", "Depression", "Depressive disorders", "Dysthymia", "Adjustment disorders", "Antidepress":

1. International Labour Organization (www.ilo.org).
2. World Health Organization (www.who.int).
3. Eurostat (http://www.ec.europa.eu/eurostat/web/main/home).
4. United States National Institute of Occupational Safety and Health (NIOSH) of the United States of America, using the NIOSH data and statistics gateway (https://www.cdc.gov/niosh/data/).
5. Finnish Institute of Occupational Health (https://www.ttl.fi/en/).
6. International Commission of Occupational Health Scientific Committee on Work Organization and Psychosocial Factors (http://www.icohweb.org/site/scientific-committee-detail.asp?sc=33).

3.2.5. Hand-searching and expert consultation

We hand-searched for potentially eligible studies in:

- Reference lists of previous systematic reviews.
- Reference lists of all included trials register records.
- Study records published over the past 24 months in the three peer-reviewed academic journals with the largest number of included studies.
- Study records that have cited the included studies (identified in Web of Science citation database).
- Collections of the review authors.

Additional experts were contacted with a list of included studies, with the request to identify potentially eligible additional studies.

3.3. Selected studies

Study selection was carried out with the Covidence software (Veritas Health Innovation). All records identified in the search were downloaded, and duplicates were identified and deleted. Afterwards, two review authors independently and in duplicate screened titles and abstracts (step 1) and then full texts (step 2) of potentially relevant records. A third review author resolved any disagreements between the two review authors. If a study record identified in the literature search was authored by a review author assigned to study selection or if an assigned review author was involved in the study, the record was re-assigned to another review author for study selection. We present the study selection in a flow chart, as per PRISMA guidelines (Liberati et al., 2009).

3.4. Eligibility criteria

The population, exposure, comparator and ouctome (PECO) criteria (Morgan et al., 2018) are described below. Our protocol paper provides

a complete, but briefer overview of the PECO criteria (see Rugulies et al., 2019 in Appendix A).

3.4.1. Types of populations

We included studies of the working-age population (≥15 years) in the formal and informal economy. Studies of children (aged <15 years) and unpaid domestic workers were excluded. Participants residing in any Member State of WHO and/or ILO and any industrial setting or occupation were included. Exposure to long working hours may potentially have further population reach (e.g., across generations for workers of reproductive age), and we acknowledge that the scope of our systematic review does not capture these populations and impacts on them.

3.4.2. Types of exposures

We included studies that defined exposure to long working hours in accordance with our standard definition (Table 1). We prioritized measures of the total number of hours worked, including in both of: main and secondary jobs, self-employment and salaried employment, whether in the informal or the formal economy. We included studies with objective (e.g., by means of time recording technology) or subjective measurements of long working hours, including studies that used measurements by experts (e.g. scientists with subject matter expertise) and self-reports by the worker, workplace administrator or manager. If a study presented both objective and subjective measurements, then we prioritized objective ones. Studies with measures from any data source, including registry data, were included. For studies that reported exposure levels differing from our standard levels (Table 1), we converted the reported levels to the standard levels if possible and reported analyses on these alternate exposure levels if impossible.

3.4.3. Types of comparators

The included comparators were participants exposed to the theoretical minimum risk exposure level: worked 35–40 h/week (Table 1). We excluded all other comparators.

3.4.4. Types of outcomes

This systematic review included three outcomes:

1. Has depression (or, in other words, depression prevalence).
2. Acquired depression (depression incidence).
3. Died from depression (depression mortality).

We included studies that defined depression in accordance with our standard definition (Table 2). Other affective disorders (e.g., bipolar disorders) were excluded. We did not expect documented ICD-10 diagnostic codes in most studies examining exposure to long working hours and its effect on depression, but expected that depression was assessed with other methods.

The following measurements of depression were regarded as eligible, as described in the protocol (Rugulies et al., 2019):

   i. Psychiatric diagnostic interview.
  ii. Diagnosis by a physician, psychologist or other qualified health professional.
 iii. Hospital admission or discharge record.
 iv. Administrative data (e.g., disability pensioning with the diagnosis of depression).
  v. Register data of treatment for depression with one or both of antidepressant medication and psychotherapy (this measurement was only included if there was documentation that the treatment was for depression specifically, and not for other disorders).
 vi. Self-administered rating scale for depression that was previously validated against a clinical measure of depression and that dichotomized respondents into cases versus non-cases (e.g., Center of Epidemiological Studies Depression Scale (CES-D)

(Radloff 1977) or Major Depression Inventory (MDI) (Bech et al., 2001)) or other validated self-administered rating scale.

vii. Medically certified cause of death.

Because the endpoint of our study was binary, studies exclusively reporting depression as a continuous variable (e.g., level of depressive symptoms) were excluded, as were all other measurements.

"More objective" measurements (e.g., diagnostic interview, administrative data or register data) and "more subjective" measurements (e.g., self-reported doctor-diagnosed depression or self-administered rating scale) were eligible. If a study presented both a "more objective" measurement and a "more subjective" measurement for the same outcome, then we prioritized the "more objective" one.

3.4.5. Types of studies

We included studies that investigated the effect of exposure to long working hours on depression for any study years and capturing any period of years. Eligible study designs were randomized controlled trials (including parallel-group, cluster, cross-over and factorial trials), cohort studies (both prospective and retrospective), case-control studies and other non-randomized intervention studies (including quasi-randomized controlled trials, controlled before-after studies and interrupted time series studies). We included a broader set of observational study designs than is commonly included, because a recent augmented Cochrane Review of complex interventions identified valuable additional studies using such a broader set of designs (Arditi et al., 2016). As we have an interest in quantifying risk and not in qualitative assessment of hazard (Barroga and Kojima, 2013), we excluded all other study designs (e.g., uncontrolled before-and-after, cross-sectional, qualitative, modelling, case and non-original studies).

Records published in any year and any language were included. Again, the search was conducted using English language terms, so that records published in any language that present essential information (i.e. title and abstract) in English were included. If a record was written in a language other than those spoken by the authors of this review or those of other reviews (Descatha et al., 2018; Descatha et al., 2020; Godderis et al., 2018; Hulshof et al., 2019; Hulshof et al., 2021a; Hulshof et al., 2021b; Li et al., 2018; Li et al., 2020; Mandrioli et al., 2018; Pachito et al., 2020; Paulo et al., 2019; Pega et al., 2020a; Teixeira et al., 2021a; Teixeira et al., 2019; Teixeira et al., 2021b; Tenkate et al., 2019) in the series (i.e., Arabic, Bulgarian, Chinese, Danish, Dutch, English, French, Finnish, German, Hungarian, Italian, Japanese, Norwegian, Portuguese, Russian, Spanish, Swedish and Thai), then the record was translated into English. Published and unpublished studies were included. Studies conducted using unethical practices were excluded (e.g., studies that deliberately exposed humans to a known risk factor to human health).

3.4.6. Types of effect measures

We included measures of the relative effect of a relevant level of exposure to long working hours on the risk of depression (prevalence, incidence and mortality), compared with the theoretical minimum risk exposure level. We included relative effect measures such as RRs, ORs or hazard ratios; however, all studies we identified reported ORs. Measures of absolute effects (e.g., mean differences in risks or odds) were converted into relative effect measures, but if conversion was impossible, they were excluded. We had aimed to convert OR into RR, however, this was for most studies not possible, as we were unable to extract information on the absolute risk of depression in the non-exposed. We therefore reported ORs and combined these effect estimates in the meta-analyses.

If a study presented estimates for the effect from two or more alternative models that had been adjusted for different variables, then we systematically prioritized the estimate from the model that provided information on the relevant confounders or mediators (at least the core variables defined in Fig. 1: age, sex and SES). We prioritized estimates from models adjusted for more potential confounders over those from

models adjusted for fewer. For example, if a study presents estimates from a crude, unadjusted model (Model A), a model adjusted for one potential confounder (e.g. age; Model B) and a model adjusted for two potential confounders (e.g., age and sex; Model C), then we prioritized the estimate from Model C. We prioritized estimates from models unadjusted for mediators over those from models that adjusted for mediators, because adjustment for mediators will introduce bias (Greenland et al., 2016; Greenland and Pearce, 2015). For example, if Model A had been adjusted for two confounders, and Model B had been adjusted for the same two confounders and a potential mediator, then we chose the estimate from Model A. We prioritized estimates from models that can adjust for time-varying confounders that are at the same time also mediators, such as marginal structural models (Pega et al., 2016), over estimates from models that can only adjust for time-invariant confounders, such as fixed-effects models (Gunasekara et al., 2014), and over estimates from models that can adjust for neither time-varying, nor time-invariant confounding. If a study presents effect estimates from two or more potentially eligible models, then we documented why we prioritized the selected model.

3.5. Extracted data

A standard data extraction form was developed and trialled until data extractors reached convergence and agreement. At least two review authors independently extracted data on study characteristics (including study authors, study year, study country, participants, exposure and outcome), study design (including study type, comparator, epidemiological model(s) used and effect estimate measure) and risk of bias (including source population representation, blinding, exposure assessment, outcome assessment, confounding, incomplete outcome data, selective outcome reporting, conflict of interest and other sources of bias). A third review author resolved conflicts in data extraction. Data were entered into and managed with Excel.

We also extracted data on potential conflict of interest in included studies. For each author and affiliated organization of each included study record, we extracted their financial disclosures and funding sources. We used a modification of a previous method to identify and assess undisclosed financial interest of authors (Forsyth et al., 2014). Where no financial disclosure or conflict of interest statements were available, we searched the name of all authors in other study records gathered for this study and published in the prior 36 months and in other publicly available declarations of interests (Drazen et al., 2010a; Drazen et al., 2010b).

3.6. Requested missing data

We requested missing data from the principal study author by email or phone, using the contact details provided in the principal study record. If we did not receive a positive response from the study author, we sent follow-up emails twice, at two and four weeks. We present a description of missing data; the study author from whom the data were requested; the dates of requests sent; the date on which data were received (if any); and a summary of the responses provided by the study authors (Appendix 2 in the Supplementary data). If we did not receive some or all of the requested missing data, we nevertheless retained the study in the systematic review as long as it fulfilled our eligibility criteria.

3.7. Assessed risk of bias

Standard risk of bias tools do not exist for systematic reviews for hazard identification or those for risk assessment in occupational and environmental health. The five such tools developed specifically for occupational and environmental health are for either or both hazard identification and risk assessment, and they differ substantially in the types of studies (randomized, observational and/or simulation studies)

and data they seek to assess (e.g., human, animal and/or *in vitro*) (Rooney et al., 2016). However, all five tools, including the Navigation Guide one (Lam et al., 2016c), assess risk of bias in human studies similarly (Rooney et al., 2016).

Consistent with using the Navigation Guide as our organizing framework, we used its risk of bias tool, which builds on the standard risk of bias assessment methods of Cochrane (Higgins et al., 2011) and the US Agency for Healthcare Research and Quality (Viswanathan et al., 2008). Some further refinements of the Navigation Guide method may be warranted (Goodman et al., 2017), but it has been successfully applied in several completed and ongoing systematic reviews (Johnson et al., 2016; Johnson et al., 2014; Koustas et al., 2014; Lam et al., 2016a; Lam et al., 2014; Lam et al., 2017; Lam et al., 2016b; Vesterinen et al., 2014). In our application of the Navigation Guide method, we drew heavily on one of its latest versions, as presented in the protocol for an ongoing systematic review (Lam et al., 2016c).

We assessed risk of bias on the individual study level and across the body of evidence for each outcome. The nine risk of bias domains included in the Navigation Guide method for human data were: (i) source population representation; (ii) blinding; (iii) exposure assessment; (iv) outcome assessment; (v) confounding; (vi) incomplete outcome data; (vii) selective outcome reporting; (viii) conflict of interest; and (ix) other sources of bias. Risk of bias or confounding ratings for all domains were: "low"; "probably low"; "probably high"; "high"; or "not applicable" (Lam et al., 2016c). To judge the risk of bias in each domain, we applied a priori instructions (Rugulies et al., 2019), which we adapted from an ongoing Navigation Guide systematic review (Lam et al., 2016c) and further described in our protocol (Rugulies et al., 2019). For example, a study was assessed as carrying "low" risk of bias from source population representation, if we judge the source population to be described in sufficient detail (including eligibility criteria, recruitment, enrolment, participation and loss to follow up) and the distribution and characteristics of the study sample to indicate minimal or no risk of selection effects.

All risk of bias assessors jointly trialled the application of the risk of bias criteria until they had synchronized their understanding and application of these criteria. Two or more study authors independently assessed the risk of bias for each study by outcome. Where individual assessments differed, a third author resolved the conflict. For each included study, we reported our risk of bias assessment at the level of the individual study by domain in a standard 'Risk of bias' table (Higgins et al., 2011). For the entire body of evidence, we presented the study-level risk of bias ratings by domains in a 'Risk of bias matrix' (Higgins et al., 2011).

3.8. Synthesised evidence (including conducted meta-analysis)

We conducted separate meta-analyses for all outcomes: Has depression, Acquired depression, and Died from depression. If we found two or more studies with an eligible effect estimate, at least two review authors independently investigated the clinical heterogeneity (Deeks et al., 2011) of the studies in terms of participants (including country, sex, age and occupation or industrial sector), level of risk factor exposure, comparator and outcomes, following our protocol (Rugulies et al., 2019). If we found that effect estimates differed considerably by WHO region, sex and/or age, or a combination of these, then we synthesised evidence for the relevant populations defined by WHO region, sex and/or age, or combination thereof. If we found effect estimates to be clinically homogenous across WHO regions, sex and age groups, we combined studies from all of these populations into one pooled effect estimate that could be applied across all combinations of WHO regions, sexes and age groups in the WHO/ILO Joint Estimates.

If we judged two or more studies for the relevant combination of WHO region, sex and age group, or combination thereof, to be sufficiently clinically homogenous to potentially be combined using quantitative meta-analysis, we tested the statistical heterogeneity of the studies using the I^2 statistic (Figueroa, 2014). If two or more clinically homogenous studies were found to be sufficiently homogenous statistically to be combined in a meta-analysis, we pooled the ORs of the studies in a quantitative meta-analysis, using the inverse variance method with a random effects model to account for cross-study heterogeneity (Figueroa, 2014). The meta-analysis was conducted in RevMan 5.3. We neither quantitatively combined data from studies with different designs (e.g. did not combine cohort studies with case-controls studies), nor did we combine unadjusted with adjusted models. We only combined studies that we judged to have a minimum acceptable level of adjustment for the three core confounders we had identified at protocol stage (Fig. 1, *Section 3.4.5*).

If quantitative synthesis was not feasible (for instance, due to different exposure levels as defined above), we synthesised the study findings narratively and identified the estimates that we judged to be the highest quality evidence available.

3.9. Conducted subgroup and sensitivity analyses

Subgroup analyses were conducted only for the main meta-analysis and comparison of interest (i.e., the meta-analysis for the comparison of worked ≥55 h/week, compared with worked 35–40 h/week). We conducted subgroup analyses by:

- WHO region.
- Sex.
- Age group.
- SES.

We also planned to conduct subgroup analyses by occupation, industrial sector and formality of the economy, but did not find evidence or receive missing data to populate these analyses.

We conducted the following sensitivity analyses:

- Studies judged to be of "high"/"probably high" risk of bias in any domain, compared with those judged as of "low"/"probably low" risk of bias in all domains.
- Studies with documented or approximated ICD-10 diagnostic codes (e.g., as recorded in administrative health records), compared with studies without ICD-10 diagnostic codes (e.g., self-reports).

We planned to also compare studies with "low" or "probably low" risk of bias from conflict of interest with studies with "high" or "probably high" risk of bias in this domain but did not conduct these sensitivity analyses because we rated all included study to have "low"/ "probably low" risk of bias from conflict of interest.

3.10. Assessed quality of evidence

We assessed the quality of evidence using a modified version of the Navigation Guide quality of evidence assessment tool (Lam et al., 2016c). The tool is based on the GRADE approach (Schünemann et al., 2011b) adapted specifically to systematic reviews in occupational and environmental health (Woodruff and Sutton 2014). An overview of GRADE and a discussion of its applicability to environmental health research has been presented by Morgan et al. (2016).

At least two review authors assessed the quality of evidence for the entire body of evidence by outcome, with any disagreements resolved by a third review author. We adapted the latest Navigation Guide instructions (Rugulies et al., 2019) for grading the quality of evidence (Lam et al., 2016c) and presented the adapted instructions in our protocol (Rugulies et al., 2019). We downgraded the quality of evidence for the following five GRADE considerations: (i) risk of bias; (ii) inconsistency that cannot be explained (or, in other words, "unexplained heterogeneity"); (iii) indirectness; (iv) imprecision; and (v) publication bias. These considerations were downgrades if they could not be

explained. If our systematic review had included ten or more studies, we generated an Egger's funnel plot to judge concerns regarding publication bias.

We graded the quality of the entire body of evidence by outcome, using the three Navigation Guide standard quality of evidence ratings: "high", "moderate" and "low" (Lam et al., 2016c). Within each of the relevant domains, we rated the concern for the quality of evidence, using the ratings "none", "serious" and "very serious". As per Navigation Guide, we started at "high" for randomized studies and "moderate" for observational studies. Quality was downgraded for no concern by nil levels (0), for a serious concern by one level (-1) and for a very serious concern by two levels (-2). We upgraded the quality of evidence for the following other reasons: (i) large magnitude of effect; (ii) presence of a dose–response relationship; and (iii) the plausibility that potential residual confounding cannot explain the effect. There had to be compelling reasons to downgrade or upgrade. If we had a serious concern for risk of bias in a body of evidence consisting of observational studies (−1 level), but had no other concerns, and had no reasons for upgrading, then we downgraded the quality of evidence by one level from "moderate" to "low".

3.11. Assessed strength of evidence

Our systematic review included studies of human data only and no studies of non-human data. The standard Navigation Guide methodology (Lam et al., 2016c) allows for rating human and non-human animal studies separately, and then combining the strength of evidence for each stream for an overall strength of evidence rating. However, the Navigation Guide also allows for rating one stream of evidence based on the domains described above (i.e., risk of bias, indirectness, inconsistency that cannot be explained, imprecisions, publication bias, large magnitude of effect, dose–response and residual confounding) to arrive at an overall rating of the quality of evidence as 'high', 'moderate' or 'low' (see above and the protocol). The approach of evaluating only the human evidence stream is consistent with the GRADE methodology that has adopted the Bradford Hill considerations (Bradford Hill, 1965; Schünemann et al., 2011a). So, using the method above based on the Navigation Guide incorporates the considerations of Bradford Hill

Table 3
Bradford Hill considerations and their relationship to GRADE and the Navigation Guide for evaluating the overall quality of the evidence for human observational studies.

Bradford Hill	GRADE	Navigation Guide
Strength	Strength of association and imprecision in effect estimate	Strength of association and imprecision in effect estimate
Consistency	Consistency across studies, i.e., across different situations (different researchers)	Consistency across studies, i.e., across different situations (different researchers)
Temporality	Study design, properly designed and conducted observational studies	Study design, properly designed and conducted observational studies
Biological Gradient	Dose response gradient	Dose response gradient
Specificity	Indirectness	Indirectness
Coherence	Indirectness	Indirectness
Experiment	Study design, properly designed and conducted observational studies	Study design, properly designed and conducted observational studies
Analogy	Existing association for critical outcomes leads to not downgrading the quality, indirectness	Existing association for critical outcomes leads to not downgrading the quality, indirectness. Evaluating the overall strength of body of human evidence allows consideration of other compelling attributes of the data that may influence certainty.

Adapted from (Schünemann et al., 2011a) and (Lam et al., 2016c).

(Table 3).

There is an additional step that is described in the protocol that integrates the quality of the evidence (the method for assessing it was described above) with other elements, including the direction of the effect, the confidence in the effect and other compelling attributes of the data that may influence our certainty to allow for an overall rating that consists of "sufficient evidence of harmfulness", "limited of harmfulness", "inadequate of harmfulness" and "evidence of lack of harmfulness" based on human evidence. This approach to evaluate only the human evidence has been applied in previous systematic reviews (Lam, 2016c, Lam, 2017) and verified by the United States of America's National Academy of Sciences (National Academies of Sciences, 2017). It also provides two steps that integrate Bradford Hill considerations (i.e., evaluating the quality of the evidence, and then evaluating the overall strength of evidence) (Bradford Hill, 1965). Finally, the GRADE quality of evidence ratings (which are the same as for Navigation Guide) are analogous to the final ratings from Bradford Hill for causality which has been described in Schünemann et al. (2011a) (Table 4).

4. Results

4.1. Study selection

Of the total of 25,550 individual study records identified in our searches, 13 study records reporting results from 22 individual studies fulfilled the eligibility criteria, and these 22 studies were included in the systematic review (Fig. 2). This included ten journal articles providing results from ten studies (Ahn 2018; Berthelsen et al., 2015; Dembe and Yao, 2016; Kato et al., 2014; Kim, 2013; Kim et al., 2016; Shields, 1999; Virtanen et al., 2012; Wang et al., 2012a; Wang et al., 2012b) and one systematic review article (Virtanen et al., 2018) providing results from 18 unpublished studies, of which ten fulfilled the eligibility criteria (Virtanen et al., 2018 – ACL; Virtanen et al., 2018 – DWECS-2000; Virtanen et al., 2018 – ELSA; Virtanen et al., 2018 – HeSSup; Virtanen et al., 2018 – HILDA; Virtanen et al., 2018 – HRS; Virtanen et al., 2018 – NLSY; Virtanen et al., 2018 – PUMA; Virtanen et al., 2018 – SHARE; Virtanen et al., 2018 – SLOSH). The remaining eight studies from the Virtanen et al. (2018) review were excluded, because their outcome was not depression but distress (n = 7) or they assessed depression with an unvalidated rating scale (n = 1). Further, we included results from an unpublished manuscript (Zadow et al., 2019; note: the article is now accepted Zadow et al., 2021) and from an analysis we (the author group) conducted of the National Longitudinal Survey of Youth (NLSY) open access database (NLSY OA Cohort, 2019).

We excluded 397 study records after full-text screening. For the 40 excluded studies that most closely resembled the included studies, the reasons for their exclusion are listed in Appendix 3. In addition, there were three studies that provided insufficient information for determining their eligibility (Laaksonen et al., 2012; Ogasawara et al., 2011; Tokuyama et al., 2003). We tried to contact the study authors for missing data to screen these studies for eligibility but did not receive the requested missing data. These three studies are therefore classified as "studies awaiting classification" in the flow chart (Fig. 2), and their characteristics are briefly described in Appendix 4 in the Supplementary data.

Of the 22 studies included in the review, 17 studies were included in one or more quantitative meta-analyses, whereas five studies were not included in any meta-analysis (Fig. 2). Of these five studies, two studies used a comparator (≤35 h/week (Berthelsen et al., 2015) and ≤50 h/week (Kato et al., 2014)) that was substantially different from our standard comparator (35–40 h/week), and the authors of these studies could not provide us with a re-analysis with a different comparator. Further, we excluded the study by Kim et al. (2016) from the meta-analysis, because it was based on the same study population as the included study by Ahn (2018). We prioritized the study by Ahn et al., because it was more recent and because the author responded to our

Table 4
Interpretation of the GRADE ratings of the overall quality of evidence and the Navigation Guide ratings for strength of evidence evaluation.

GRADE rating for quality of evidence	Interpretation of GRADE rating	Navigation Guide rating for strength of evidence for human evidence	Interpretation of Navigation Guide rating
High	There is high confidence that the true effect lies close to that of the estimate of the effect.	**Sufficient evidence of harmfulness**	A positive relationship is observed between exposure and outcome where chance, bias, and confounding can be ruled out with reasonable confidence. The available evidence includes results from one or more well-designed, well conducted studies, and the conclusion is unlikely to be strongly affected by the results of future studies.
Moderate	There is moderate confidence in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.	**Limited evidence of harmfulness**	A positive relationship is observed between exposure and outcome where chance, bias, and confounding cannot be ruled out with reasonable confidence. Confidence in the relationship is constrained by such factors as: the number, size, or quality of individual studies, or inconsistency of findings across individual studies. As more information becomes available, the observed effect could change, and this change may be large enough to alter the conclusion.
Low	The panel's confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect	**Inadequate evidence of harmfulness**	The available evidence is insufficient to assess effects of the exposure. Evidence is insufficient because of: the limited number or size of studies, low quality of individual studies, or inconsistency of findings across individual studies. More information may allow an assessment of effects.
Very Low	There is little confidence in the effect estimate: the true effect is likely to be substantially different from the estimate of effect.		

Footnote: Adapted from (Schünemann et al., 2011a) and (Lam et al., 2016c).

request for re-analysis of the data. Finally, we excluded the studies by Dembe and Yao (2016) and Virtanen et al., 2018 – NLSY from the meta-analyses, because these two studies were based on the same study population as the NLSY open access database cohort that we analysed (NLSY OA Cohort, 2019). We prioritized the open access data analysis over the published analyses by Dembe and Yao (2016) and Virtanen et al., 2018 – NLSY because in our analyses we could apply all of the standard exposure categories as described in our protocol (Rugulies et al., 2019).

4.2. Characteristics of included studies

The characteristics of the included studies are summarized in Table 5.

4.2.1. Study type

All 22 included studies were cohort studies, with 21 being prospective and one being retrospective in design. Of the 22 studies, all examined risk of acquiring depression, with 21 studies examining first onset of depression and one study recurrence of depression among participants who had reported a previous depression but who were free from depression at the time of the baseline assessment (Wang et al., 2012b). The effect estimates reported in all studies were ORs for an eligible category of exposure to long working hours, compared with standard working hours (or a similar comparator). All studies adjusted for our three pre-specified confounders (Fig. 1 and Table 5).

4.2.2. Population studied

The 22 included studies captured 109,906 workers (51,324 females and 58,582 males). Twenty-one studies included both female and male workers, whereas one study included male workers only (Kato et al., 2014). The age range was from 17 to 71 years. When studies reported a mean age, this was most often in the 40s (Table 5 for details).

By WHO region, most studies examined populations in the Americas (nine studies of two countries) followed by Europe (eight studies, including seven studies of five countries, plus one study combining data from 28 countries), followed by the Western Pacific (five studies of three countries). The most commonly studied countries were the United States of America (six studies), Canada (three studies), and Australia, Denmark, the Republic of Korea and the United Kingdom of Great Britain and Northern Ireland (two studies each).

Only one study provided a detailed breakdown by occupation and industrial sector (Ahn, 2018). Five studies provided limited information on occupation, industrial sector or both (Kato et al., 2014; Kim, 2013; Virtanen et al., 2012; Wang et al., 2012a), and one study included only one specific occupational group (i.e., nurses; Berthelsen et al., 2015). See Table 5 for details. The other studies did not provide information on industrial sector or occupation.

4.2.3. Exposure studied

All studies measured exposure to long working hours by self-report, either by pen-and-paper-survey (four studies), face-to-face-survey (three studies), telephone survey (four studies), an interview (unclear if face-to-face or telephone) (two studies) or did not specify which of these methods were used (nine studies). No included study used non-self-reported measures, such as official or company records of hours worked.

Only two of the 22 included studies (NLSY OA Cohort, 2019; Zadow et al., 2019) provided the standard exposure categories that we had predefined in the protocol. We therefore attempted to contact all study authors asking them to either provide us with the original data or conducting a re-analysis of the data using our standard exposure categories. The author of one study provided us with the original data (Kim, 2013), and the authors of three studies re-analysed the data according to our request (Ahn, 2018; Wang et al., 2012a; Wang et al., 2012b), yielding a total of six studies providing the standard exposure categories. In addition, five published studies (Dembe and Yao, 2016; Kato et al.,
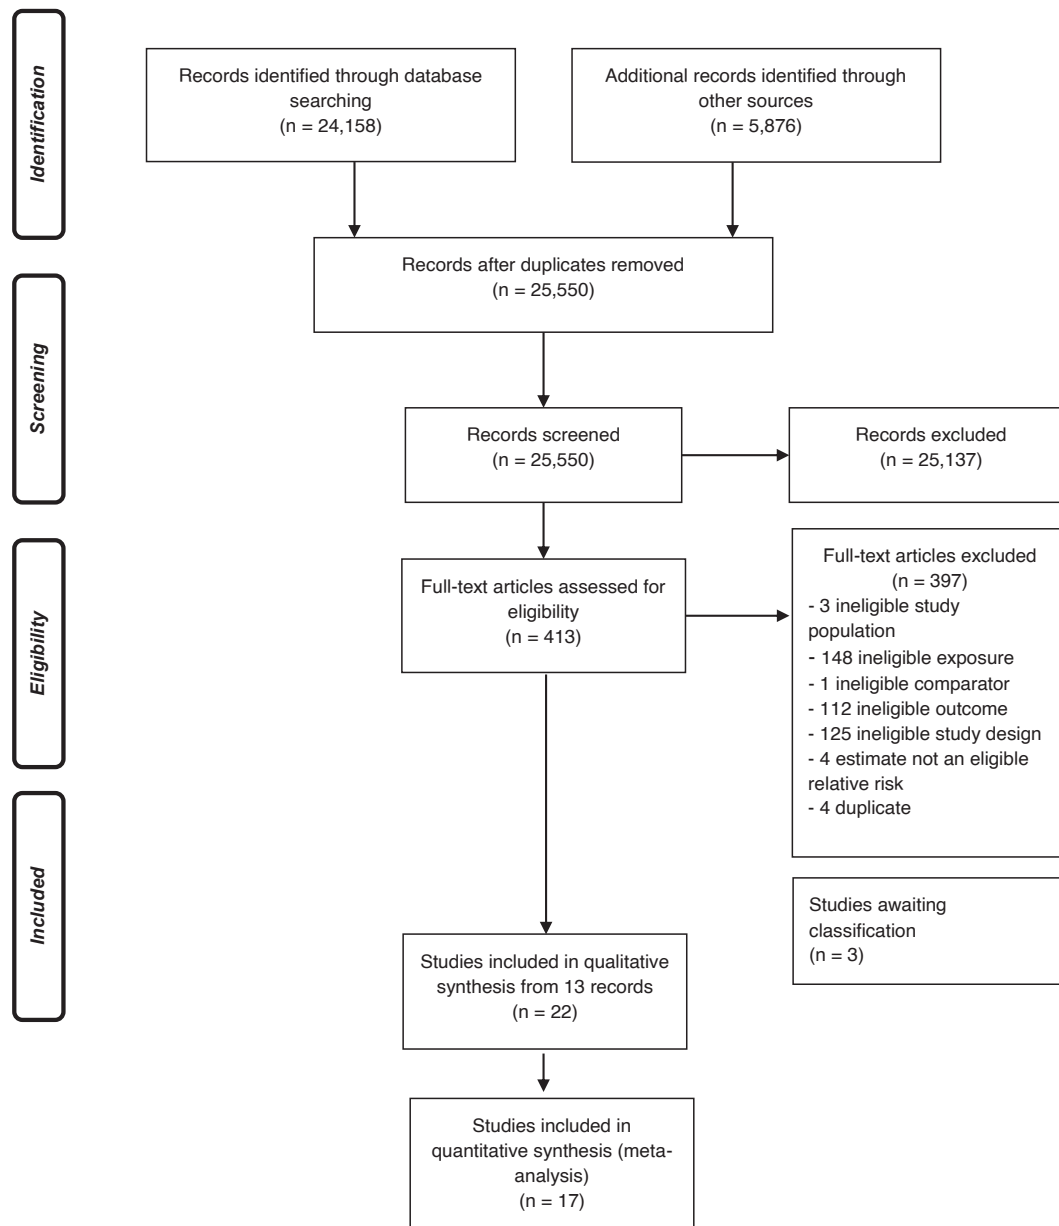

Fig. 2. Flow diagram of study selection.

2014; Kim et al., 2016; Shields, 1999; Virtanen et al., 2012) and all ten unpublished studies from the Virtanen et al. review (Virtanen et al., 2018) reported effect estimates for exposure categories that we regarded as similar enough to our standard exposure categories. One study provided exposure categories (i.e., 35.5–37.5 h/week and > 37.5 h/week) that we judged as non-comparable to our standard exposure categories (Berthelsen et al., 2015), because these exposure categories included values of our standard comparator (35–40 h/week).

4.2.4. Comparator studied

Nineteen studies used the standard comparator of 35–40 h/week, including the four studies that were re-analysed on our request (Ahn, 2018; Kim, 2013; Wang et al., 2012a; Wang et al., 2012b). Of the remaining three studies, one study used a comparator that we judged as similar (30–40 h/week) (Dembe and Yao, 2016). Two studies used a comparator that we judged as non-comparable to the standard comparator, because the comparator either included very low working hours (1–35 h/week) (Berthelsen et al., 2015) that may indicate reduced work ability and existing health problems, or working hours of 1–50 h/

week (Kato et al., 2014) that included both very low working hours and working hours that overlapped with our standard exposure categories.

4.2.5. Outcomes studied

Of the three outcomes included in this systematic review, we found no eligible study for the following two outcomes:

- "Has depression" (depression prevalence); and
- "Died from depression" (depression mortality).

Of the 22 studies, all 22 studied the outcome "Acquired depression" (depression incidence), 21 studies capturing the incidence of first onset of depression (first time depression incidence) and one study investigating acquiring depression again (recurrence of depression) (Wang et al., 2012b).

Acquiring depression was measured using:

- A self-administered rating scale in 15 studies (Ahn 2018; Berthelsen et al., 2015; Kato et al., 2014; Kim et al., 2016; Virtanen et al., 2018 –

Table 5
Characteristics of included studies in the systematic review of long working hours and depression.

Fig. 3. Summary of risk of bias, Acquired depression (depression incidence).

o 1 study used the Symptom Checklist Core Depression 6-item scale (SCL-CD6).

o 1 study used the Patient Health Questionnaire 9 (PHQ-9).

- A clinical diagnostic interview in four studies (Shields, 1999; Virtanen et al., 2012; Wang et al., 2012a; Wang et al., 2012b).
- A comprehensive interview assessing diagnosed depression and treatment for depression in one study (Kim 2013).
- A question about doctor-diagnosed depression in two studies (Dembe and Yao, 2016; NLSY OA Cohort, 2019).

4.2.6. Statistical modelling

All 22 studies adjusted or stratified for the three key potential confounders (i.e., sex, age and SES), and most studies adjusted for further variables, for example marital status, cohabitation or children living at home. When studies provided multiple statistical models with different adjustments, we aimed for selecting estimates that were adjusted for as many confounders as possible while not being adjusted for potential mediation. See Appendix 5 in the Supplementary data for a description of our rationale for selecting specific estimates from the included studies. For six studies, we conducted re-analyses of the original data, giving us control over the statistical modelling (Ahn, 2018; Kim, 2013; NLSY OA Cohort, 2019; Wang et al., 2012a; Wang et al., 2012b; Zadow et al., 2019).

4.3. Risk of bias at individual study level

We assessed risk of bias based on the information we retrieved from the included study records and additional records on the included studies. For the ten previously unpublished studies presented in the Virtanen et al. (2018) systematic review, risk was assessed based on both information provided by Virtanen et al. (2018) and information from previous publications on the cohorts and datasets analysed by Virtanen et al. (2018). This systematic review only included evidence on one eligible outcome: "Acquired depression" (depression incidence). The risk of bias rating for each domain for all 22 included studies for this outcome are presented in Fig. 3. The justification for each rating for each domain by included study is presented in risk of bias tables in Appendix 6 in the Supplementary data.

4.3.1. Selection bias (not representing source population)

We rated the risk of this selection bias as probably low for 19 studies and as probably high for three studies. We rated the risk of bias as probably low, because the studies comprised large populations of working-age individuals and all studies described their sample criteria extensively, enabling comparisons with the source population. Response rates differed considerably between the studies, however, a low response rate in a cohort study does not necessarily indicate a high risk of bias of the observed association between the exposure and the outcome; it first and foremost means that results cannot necessarily be generalized to the source population (Olsen, 2014; Rothman et al., 2013b), although this has been controversially debated (Ebrahim and Davey Smith, 2013; Rothman et al., 2013a). Under certain circumstances, non-response can introduce bias (Munafó et al., 2018), such as when selection out of the study is differential by exposure status; thus, we cannot rule out bias, but we judged the risk of bias as overall probably low. There are three exception, though: the studies by Berthelsen et al. (2015), Dembe and Yao (2016) and by Wang et al. (2012b). Berthelsen et al. (2015) deliberately did not exclude individuals with depression at baseline, but instead adjusted for baseline depression scores in the analyses. While this adjustment is likely to have reduced bias in the analyses, we are still concerned that individuals with prevalent depression may have been selected into specific working time arrangements. Dembe and Yao (2016) measured exposure as working hours per week, averaged over the whole 32-year observation period. Depression was not assessed at the beginning of the study, but at some point during the study. Thus, several measures of working hours were

collected at a time when some individuals might have already had a depression. It is possible that these individuals had been selected into jobs with specific work time arrangements due to their depression, and that these individuals were at increased risk of being diagnosed with depression during follow-up. Consequently, we rated this study as being of probably high risk of bias. Wang et al. (2012b) examined risk of recurrent depression in a cohort of individuals who had a lifetime history of depression but were free of depression at the time of the baseline measurement. It is likely that frequency and severity of past depressive episodes differed in this cohort, and it is possible that individuals with more frequent or more severe previous depressive episodes were both selected into specific work time arrangements and at increased risk of being diagnosed with a recurrent depression during follow-up. Consequently, we rated this study as of probably high risk of bias.

4.3.2. Performance bias

We rated the risk of this bias as probably low for all 22 studies. In experimental studies, such as clinical trials, knowledge about assignment to either intervention or control group may influence behaviour or reporting of participants and can therefore severely bias results. This is of lesser concern in the observational studies included in this review, where participants were not assigned to a treatment or control group but first reported information about exposure and health conditions, then were categorized by researchers into different exposure groups and then were followed-up for assessing incidence of the outcome. We cannot rule out bias, as for example it is possible that individuals sensing that the study might be about working hours and health may over- or underreport numbers of working hours, but we regard the likelihood of this possible risk of bias to be low. None of the studies reported whether study personnel, such as statisticians conducting the analyses, were blinded to the exposure and/or outcome status of the participants. But even if they were unblinded, we doubt that this would have influenced the statistical analyses or reporting.

4.3.3. Detection bias (exposure assessment)

We rated the risk of this bias as probably low for 19 studies, and as probably high risk for three studies. Working hours were recorded in all studies by self-report by the workers; no study used "more objective" measures such as administrative records. We are not concerned about bias here, as we assume that individuals, who are free of depression, are able to estimate their weekly working hours reasonably accurately. This assumption is supported by results from a study by Imai et al. (2016). For three studies, though (Berthelsen et al. (2015), Dembe and Yao (2016) and Wang et al. (2012b)), we rated the risk of this bias as probably high, because it was possible that some participants in these studies either had a current depression (Berthelsen et al., 2015; Dembe and Yao, 2016) or an incomplete recovery from a previous depression (Wang et al., 2012b) when they reported their weekly working hours. This might have introduced bias, as there is evidence that individuals with depression tend to overestimate the adversity and negativity of their environment (Harmer et al., 2009). Berthelsen et al. (2015) deliberately did not exclude individuals with depression at baseline, but instead adjusted for baseline depression scores in the analyses. While this adjustment is likely to have reduced bias in the analyses, we are still concerned with self-reported working hour assessments of individuals with prevalent depression. Dembe and Yao (2016) included measures of working hours over 32 years, including several years before they assessed depression, and therefore did not know the depression status of their participants at the time of some of the exposure assessments (see comments in Section 4.3.1 on selection bias [not representing source population] above). Wang et al. (2012b) examined recurrence of depression among participants with a lifetime history of depression. Although participants with a current depressive episode at baseline were excluded from the analyses, it is possible that incomplete recovery from a previous depressive episode may have affected both the reporting of hours worked at baseline and the risk of depression during follow-up.

4.3.4. Detection bias (outcome assessment)

We rated the risk of this bias as low for four studies, probably low for 14 studies and probably high for four studies. The four studies rated as having low risk of bias (Shields, 1999; Virtanen et al., 2012; Wang et al., 2012a; Wang et al., 2012b) all used the gold standard method for assessing depression in epidemiological studies: a clinical diagnostic interview (Drill et al., 2015). The 14 studies rated as of probably low risk of bias either used a self-administered rating scale that had previously been validated against clinical measures of depression (14 studies) or conducted a comprehensive interview with the participants to identify diagnosis or treatment of depression that was then coded into ICD-9 codes (Kim, 2013). Of the four studies rated as probably high, two used a simple question to assess if the participants ever had a doctor-diagnosed depression (Dembe and Yao, 2016; NLSY OA Cohort, 2019), and we were concerned that several cases of depression were missed with this rather crude method to recall episodes of depression. The two other studies rated as of probably high risk of detection bias were the Virtanen et al., 2018 – HRS study and the Virtanen et al., 2018 – SLOSH study from the systematic review by Virtanen et al. (2018). For the Virtanen et al., 2018 – HRS study, Virtanen et al. (2018) stated that the outcome measure of this study was "depressive symptoms" without naming the instrument. From our knowledge of the study, we assume that the instrument used was the CES-D, but as we cannot be sure and, having indirect evidence only, we rated this study as of probably high risk of bias in this domain. For the Virtanen et al., 2018 – SLOSH study, Virtanen et al. (2018) stated that the outcome measure of this study was "depressive symptoms" measured with the "Symptom Check List, SCL". From our knowledge of this study, we assume that the instrument used was the SCL-CD6, but as we cannot be sure and, having indirect evidence only, we rated this study as having probably high risk of detection bias.

4.3.5. Confounding

We rated the risk of confounding as low for two studies, probably low for 19 studies and probably high for one study. We rated the studies by Ahn (2018) and Berthelsen et al. (2015) as carrying low risk of confounding, because it controlled for all first-tier confounders (i.e., age, sex and SES) and also for all second-tier confounders (i.e., job group, industry and country), either by adjusting, stratifying or study design (e.g., only including employees from a specific job group into the study), as we had prespecified in our protocol (Rugulies et al., 2019). The 19 studies rated as of probably low risk of confounding adjusted for all first-tier confounders but not all second-tier confounders. The one study rated as probably high risk in this domain (Shields, 1999) adjusted for all first-tier and some second-tier confounders, but also further adjusted for a measure of work stress (job strain), which we regard as over-adjustment. One of the components of job strain is high psychological demands (Karasek, 1979), which might conceptually overlap with exposure to long working hours. Further, it seems reasonable to assume that exposure to long working hours can cause the experience that work is highly psychologically demanding, which would make high psychological demands a potential mediator, a step in the causal pathway, for the association between working long hours and risk of depression. Adjusting for a mediator would introduce bias into the analyses; we therefore rated the study by Shields (1999) as having high risk of confounding.

However, if our assumption that exposure to long working hours would cause the work to be highly psychologically demanding was wrong, and instead highly psychologically demanding work would cause long working hours (e.g., because working long hours would be a way to handle high psychological demands at work) and, if further, high psychological demands at work would increase risk of depression, then high psychological demands would be a potential confounder for the association between exposure to long working hours and risk of depression. In this case, our decision to rate the study by Shields (1999) as of high risk of confounding would have been wrong. Further, in this case, our a priori decision to select, if possible, estimates that were not adjusted for high psychological demands or other psychosocial work

environment factors, would also have been wrong, and the estimates we selected would have been at risk of being confounded. We were aware of this when we wrote the protocol of the systematic review and made the conscious decision to assume that other psychosocial work environment factors, including psychological demands, are mediators rather than confounders. We acknowledge that this assumption can be contested.

Other psychosocial work environment factors could not only be confounders or mediators but also be effect modifiers, i.e. it is possible that the interaction of exposure to long working hours with other psychosocial work environment factors would cause a stronger or a weaker effect on risk of depression. In the job strain model, it is assumed that high psychological demands in combination with high job control would not be health-hazardous but rather health-beneficial, because this combination would enhance learning and feelings of mastery (Theorell and Karasek, 1996). The combination of high psychological demands with low job control, on the other hand, would inhibit learning, cause strain and ultimately be health-hazardous (Theorell and Karasek, 1996). Empirically, it has indeed been shown that high psychological demands in themselves are not associated with risk of depression, whereas the combination of high psychological demands and low job control is associated with a higher risk of depression (Madsen et al., 2017; Theorell et al., 2015). Similarly, it is conceivable that long working hours in combination with low job control, but also in combination with other psychosocial work environment factors (e.g., low leadership quality or high role conflicts), could have a stronger effect on risk of depression than without these other factors. If this was the case, then our decision not to adjust for other psychosocial work environment factors would remain the correct decision, because adjusting for an effect modifier would give biased results. The appropriate approach would have been to test for interaction, however, this was beyond the scope of this review.

4.3.6. Selection bias (incomplete outcome data)

We rated the risk of this bias as probably low for four studies and probably high for 18 studies. Depression is often, although not always, episodic and self-limiting with a high recurrence rate (Kessler et al., 2003). This constitutes a challenge for epidemiological research. A cohort study measuring depression at baseline and some years later at follow-up, will not be able to identify those episodes of depression that occurred after baseline but were no longer present at the time of the follow-up measurement. This is of particular concern in those studies that measured depression at follow-up with a self-administered rating scale that asked about symptoms of depression during the last one or two weeks only. Consequently, we rated the 15 studies using a self-administered rating scale and the two studies using a simple question about doctor-diagnosed depression (Dembe and Yao, 2016; NLSY OA Cohort, 2019) as of probably high risk of selection bias due to incomplete outcome data. One study, Virtanen et al. (2012), used a clinical diagnostic interview covering depressive episodes during the last 12 months, and this study was also rated as of probably high risk of bias, because the follow-up period was very long (5.8 years). As carrying low risk of this selection bias, we rated Shields (1999), Wang et al. (2012a) and Wang et al. (2012b) that used a clinical diagnostic interview with a relatively short follow-up period of two years (Shields, 1999) and one year (Wang et al., 2012a; Wang et al., 2012b), respectively, and Kim (2013) because in this study doctor-diagnosed depression and treatment for depression was assessed every six months in a comprehensive interview.

4.3.7. Bias due to selective outcome reporting

We rated this bias as of low risk for all 22 studies. None of the included studies had a pre-specified study protocol, but all the studies' outcomes were reported in the results sections of the study record as outlined in the methods sections.

4.3.8. Conflict of interest

We rated all 22 studies as of low risk of this bias, as we did not find

any indication of a conflict of interest. More specifically, the studies:

- Did not receive support from a company or other entity with a financial interest in the study findings;
- Were funded by public research agencies or related organizations that were free from commercial interests in the study findings;
- Were authored only by persons who were not affiliated with companies or other entities with vested interests; and/or;
- Had no conflict of interest declared by study authors.

4.3.9. Other risk of bias

We identified one additional potential risk of bias that applied to 19 of the 22 studies, that is a probably high risk of bias due to lacking information on episodes of depression earlier in the life preceding the time of baseline assessment of depression. While we are confident that 19 of the 22 studies did not include individuals with a prevalent depression at baseline (see Section 4.3.1 on selection bias [not representing source population]), we are not confident that most studies were able to identify depression episodes that occurred during the lifetime before baseline assessment. This is a problem, because if there was a depressive episode before baseline assessment, the outcome of the study would change from "acquired depression for the first time in life" (first time incident depression) to "acquired depression again" (recurrent depression). Whether the association between a risk factor (e.g., exposure to long working hours) and depression is different for first time incidence of depression and recurrent depression is difficult to estimate. This may depend on various factors, such as the severity of the first depression; if the first depression was treated or not; the time span between the first and the recurrent depression; or whether there was only one depressive episode or multiple depression episodes before the measurement of the recurrent depression in the study (Burcusa and Iacono, 2007; Kessler et al., 2003; Moffitt et al., 2010). Thus, that studies were not able to measure lifetime depression prior to baseline assessment does not necessarily mean that estimates were biased, but we judged this as indirect evidence for potential bias and consequently rated the risk of bias as being probably high. As having probably low risk of bias, we rated the studies by Kim et al. (2013) that used comprehensive interviews to assess previous diagnosis and treatment for depression, and Wang et al. (2012a) and Wang et al. (2012b) that assessed lifetime prevalence of depression with a clinical diagnostic interview. Also for these three studies it is possible that previous depression episodes were missed, either because they were not diagnosed or treated (Kim, 2013) or because individuals had forgotten about earlier episodes of depression in the assessment of life-time prevalence (Wang et al., 2012a; Wang et al., 2012b); however, we assessed this risk as probably low. Two studies used a simple question to assess life-time depression before baseline (Dembe and Yao, 2016; NLSY OA Cohort, 2019). Although such a question is superior to not assessing life-time depression at all, we are still concerned that this is not sufficient for measuring lifetime depression; consequently we rated these two studies also as of probably high risk of this other bias.

4.4. Synthesis of results

This systematic review only included evidence on one eligible outcome: "Acquired depression" (depression incidence). We report findings from the three eligible comparisons included in this systematic review.

4.4.1. Comparison: worked 41–48 h/week compared with worked 35–40 h/week

A total of eight studies with 49,392 participants reported effect estimates on the risk of acquiring depression when working 41–48 h/week, compared with working 35–40 h/week. These studies were somewhat heterogeneous in their definition of the exposure category and/or the comparator. Six studies (Ahn, 2018; Kim, 2013; NLSY OA

Cohort, 2019; Wang et al., 2012a; Wang et al., 2012b; Zadow et al., 2019) used the standard exposure categories, as defined in our protocol (Rugulies et al., 2019), and two studies (providing three estimates) used exposures categories that were non-standard but judged by us as similar enough for combining them in the meta-analysis (Shields, 1999; Virtanen et al., 2012). The non-standard exposure categories were >40 h/week compared with 35–40 h/week (Shields, 1999) and 45 h/week compared with 35–40 h/week (Virtanen et al., 2012), respectively. Despite these definitional differences in exposure, we judged these studies to be sufficiently homogenous to be combined in one meta-analysis. The eight studies reported nine eligible effect estimates, with one study providing two estimates: one each for women and men. Fig. 4 depicts the forest plot for this meta-analysis of these eight included studies. We retained all nine individual effect estimates in the forest plot (rather than combining the effect estimates for women and men from the same study). Compared with working 35–40 h/week, working 41–48 h/week had similar odds of acquiring a depression when followed up between 1 and 10 years (OR 1.05, 95% CI 0.86 to 1.29, eight studies with nine estimates, 49,392 participants, I^2 46%). When we excluded the one study on recurrent depression (Wang et al., 2012b), the pooled estimate remained virtually unchanged (OR 1.04, 95% CI 0.83 to 1.29, seven studies with eight estimates, 48,997 participants, I^2 52%).

When comparing the estimates from the six studies using the standard exposure categories to the estimates from the two studies using approximated exposure categories, we did not find a statistically significant difference (p = 0.81, see Appendix 7 in the Supplementary data).

Fourteen of the 22 studies from this review were not included in this meta-analysis. The ten studies from the Virtanen et al. (2018) review were not included, because they only reported estimates for exposure categories for ≥55 h/week. The study by Berthelsen et al. (2015) was not included, because it used as the comparator all working hours of ≤35 h/week and used as exposures weekly working hours of 35.5–37.5 (OR 1.38, 95% CI 0.92–2.06) and >37.5 (OR 1.04, 95% CI 0.62–1.75), respectively. The study by Kato et al. (2014) was not included, because it used as the comparator all working hours of ≤50 h/week and used as exposures working hours of 50.1–60 h/week (OR 1.14, 95% CI 0.70–1.86) and ≥60 h/week (OR 4.04, 95% CI 1.68–9.75). The study by Dembe and Yao (Dembe and Yao, 2016) was not included, because it was based on the same study population as the NLSY OA Cohort (2019) that was included. Dembe and Yao reported odds ratios of 0.96 (95% CI 0.80–1.15), 1.04 (95% CI 0.79–1.38) and 0.82 (95% CI 0.50–1.35) for 41–50 h/week, 51–60 h/week and >60 h/week, respectively, compared with 30–40 h/week. Kim et al (2016) was not included, because it was based on the same study population as Ahn (2018) that was included. Kim et al. (2016) reported odds ratios of 0.92 (95% CI 0.65–1.30), 1.09 (95% CI 0.82–1.46) and 1.92 (95% CI 1.30–2.85) for 41–52 h/week, 53–68 h/week and >68 h/week, respectively, compared with 35–40 h/week.

4.4.2. Comparison: worked 49–54 h/week compared with worked 35–40 h/week

A total of eight studies with 49,392 participants reported effect estimates on the risk of acquiring depression when working 49–54 h/week, compared with working 35–40 h/week. These studies were also somewhat heterogeneous in their definition of the exposure category and/or the comparator. Six studies (Ahn, 2018; Kim, 2013; NLSY OA Cohort, 2019; Wang et al., 2012a; Wang et al., 2012b; Zadow et al., 2019) used the standard exposure categories, which we had defined in the protocol (Rugulies et al., 2019). Two studies (providing three estimates) used exposures categories that were non-standard but judged (by us) as sufficiently similar to combine them in the meta-analysis (Shields, 1999; Virtanen et al., 2012). The non-standard exposure categories were >40 h/week compared with 35–40 h/week (Shields, 1999) and 50 h/week compared with 35–40 h/week (Virtanen et al., 2012). Despite these definitional differences in exposure, we judged these studies to be
Fig. 4. Main meta-analysis, Acquired depression, worked 41–48 h/week compared with worked 35–40 h/week.

sufficiently homogenous to be combined in one meta-analysis. The eight studies reported nine eligible effect estimates, with one study providing two estimates, namely one each for women and men. Fig. 5 depicts the forest plot for this meta-analysis of the eight included studies. We retained all nine individual effect estimates in the forest plot. Compared with working 35–40 h/week, working 49–54 h/week had similar odds of acquiring a depression when followed up between 1 and 10 years (OR 1.06, 95% CI 0.93 to 1.21, eight studies with nine estimates, 49,392 participants, I^2 40%). When we excluded the one study on recurrent depression (Wang et al., 2012b), the pooled estimate also remained virtually unchanged (OR 1.05, 95% CI 0.92 to 1.19, seven studies with eight estimates, 48,997 participants, I^2 32%).

When comparing the estimates from the six studies using the standard exposure categories with the estimates from the two studies using approximated exposure categories, we did not find a statistically significant difference (p = 0.54; see Appendix 7).

Fourteen of the 22 studies included in this systematic review were not included in this meta-analysis. The ten studies from the review by Virtanen et al. (2018) were not included, because they only reported estimates for exposure categories for ≥55 h/week. Berthelsen et al. (2015) was not included, because this study used as the comparator all working hours of ≤35 h/week and as exposure categories working hours of 35.5–37.5 per week (OR 1.38, 95% CI 0.92–2.06) and >37.5 per week (OR 1.04, 95% CI 0.62–1.75), respectively. Kato et al. (2014) was not included because it used as the comparator all working hours of ≤50 h/week and as exposures working hours of 50.1–60 h/week (OR 1.14, 95% CI 0.70–1.86) and ≥60 h/week (OR 4.04, 95% CI 1.68–9.75). The Dembe and Yao study (Dembe and Yao, 2016) was not included, since it was based on the same study population as the NLSY OA Cohort (2019) that was included. Dembe and Yao reported odds ratios of 0.96 (95% CI 0.80–1.15), 1.04 (95% CI 0.79–1.38) and 0.82 (95% CI 0.50–1.35) for 41–50 h/week, 51–60 h/week and >60 h/week, respectively, when compared with 30–40 h/week. Kim et al. (2016) was not included, because it was based on the same study population as Ahn (2018) that was included. Kim et al. (2016) reported odds ratios of 0.92 (95% CI

0.65–1.30), 1.09 (95% CI 0.82–1.46) and 1.92 (95% CI 1.30–2.85) for 41–52 h/week, 53–68 h/week and >68 h/week, respectively, compared with 35–40 h week.

4.4.3. Comparison: Worked ≥55 h/week compared with worked 35–40 h/week

A total of 17 studies with 91,142 participants reported effect estimates on the risk of acquiring depression when working ≥55 h/week, compared with working 35–40 h/week. These studies were also somewhat heterogeneous in their definition of the exposure category and/or the comparator. Fifteen studies (Ahn, 2018; Kim, 2013; NLSY OA Cohort, 2019; Virtanen et al., 2018 – ACL; Virtanen et al., 2018 – DWECS; Virtanen et al., 2018 – ELSA; Virtanen et al., 2018 – HESSUP; Virtanen et al., 2018 – HILDA; Virtanen et al., 2018 – HRS; Virtanen et al., 2018 – PUMA; Virtanen et al., 2018 – SHARE; Virtanen et al., 2018 – SLOSH; Wang et al., 2012a; Wang et al., 2012b; Zadow et al., 2019) used the standard exposure categories, defined in the protocol (Rugulies et al., 2019). Two studies (with three eligible individual effect estimates) used exposures categories that were non-standard but judged by us as similar enough for combining them in one meta-analysis (Shields, 1999; Virtanen et al., 2012). The non-standard exposure categories were >40 h/week compared with 35–40 h/week (Shields, 1999) and, respectively, 55–60 h/week compared with 35–40 h/week (Virtanen et al., 2012). Despite these definitional differences in exposure, we judged these studies to be sufficiently homogenous to all be combined in the one meta-analysis. The 17 studies reported 18 eligible effect estimates, with one study providing two estimates: one each for women and men. Fig. 6 depicts the forest plot for this meta-analysis of the 17 included studies. We retained all 18 individual effect estimates in the forest plot (rather than combining the effect estimates for women and men from the same study). Compared with working 35–40 h/week, working ≥55 h/week had similar odds of acquiring a depression when followed up between 1 and 10 years (OR 1.08, 95% CI 0.94 to 1.24, 17 studies with 18 estimates, 91,142 participants, I^2 46%). When we excluded the one study on recurrent depression (Wang et al., 2012b), the pooled effect estimate
Fig. 5. Main meta-analysis, Acquired depression, worked 49–54 h/week compared with worked 35–40 h/week.
Fig. 6. Main meta-analysis, Acquired depression, worked ≥ 55 h/week compared with worked 35–40 h/week.

remained virtually unchanged (OR 1.08, 95% CI 0.94 to 1.25, 16 studies with 17 estimates, 90,747 participants, I^2 49%).

When comparing the estimates from the 15 studies using the standard exposure categories to the estimates from the two studies using approximated exposure categories, we did not find a statistically significant difference (p = 0.48, see Appendix 7 in the Supplementary data).

Five of the 22 studies included in this systematic review were not included in this meta-analysis. Berthelsen et al. (2015) was not included, because it used as the comparator all working hours of ≤35 h/week, and because it used as exposures weekly working hours of 35.5–37.5 (OR 1.38, 95% CI 0.92–2.06) and >37.5 (OR 1.04, 95% CI 0.62–1.75). Kato et al. (2014) was not included, because it used the comparator of all working hours of ≤50 h/week and the exposures of weekly working hours of 50.1–60 (OR 1.14, 95% CI 0.70–1.86) and ≥60 (OR 4.04, 95% CI 1.68–9.75). Dembe and Yao (Dembe and Yao, 2016) and Virtanen et al., 2018 – NLSY were excluded from the meta-analysis, because they were both based on the same study population as NLSY OA Cohort (2019) that we did include in the meta-analysis. Dembe and Yao reported odds ratios of 0.96 (95% CI 0.80–1.15), 1.04 (95% CI 0.79–1.38) and 0.82 (95% CI 0.50–1.35) for 41–50 h/week, 51–60 h/week and >60 h/week, respectively, when compared with 30–40 h/week. Virtanen et al., 2018 – NLSY reported an odds ratio of 1.06 (95% CI 0.77–1.44) for the comparison of ≥55 h/week versus 35–40 h/week. Kim et al. (2016) was also excluded, since it was based on the same study population as Ahn (2018) that we did include. Kim et al. (2016) reported odds ratios of 0.92 (95% CI 0.65–1.30), 1.09 (95% CI 0.82–1.46) and 1.92 (95% CI 1.30–2.85) for 41–52 h/week, 53–68 h/week and >68 h/week, respectively, compared with 35–40 h week.

4.5. Additional analyses

4.5.1. Subgroup analyses

We conducted subgroup analyses for the comparison between the group that worked ≥55 h/week and the group that worked 35–40 h/week. These analyses include subgrouping by WHO region, sex, age and SES (Table 6). For the subgroup analysis by WHO region, data were available for all studies from the main analysis (n = 17), whereas the subgroup analyses could only be performed for selected studies by sex (n = 6) (Ahn, 2018; Kim, 2013; NLSY OA Cohort, 2019; Shields 1999; Wang et al., 2012a; Zadow et al., 2019), age (n = 5) (Ahn, 2018; Kim, 2013; Wang et al., 2012a; Zadow et al., 2019) and SES (n = 5) (Ahn, 2018; Kim, 2013; NLSY OA Cohort, 2019; Wang et al., 2012a; Zadow et al., 2019). We could not perform subgroup analyses by occupation,

Table 6
Summary of results from subgroup analyses on exposure to long working hours (≥55 h/week) and acquiring depression.

Subgroup	Pooled odds ratio (95% confidence interval)
WHO region (n = 17 studies)	
Americas	1.09 (0.89 to 1.34)
Europe	1.06 (0.82 to 1.36)
Western Pacific	1.05 (0.70 to 1.58)
p for subgroup differences:	0.97
Sex (n = 6 studies)	
Women	1.15 (0.76 to 1.75)
Men	1.21 (1.01 to 1.44)
p for subgroup differences:	0.85
Age (n = 5 studies)	
15–19 years	Not estimable
20–24 years	1.49 (0.49 to 4.58)
25–29 years	0.84 (0.51 to 1.41)
30–34 years	1.06 (0.67 to 1.65)
35–39 years	1.56 (0.87 to 2.81)
40–44 years	1.15 (0.92 to 1.45)
45–49 years	1.09 (0.48 to 2.46)
50–54 years	1.25 (0.62 to 2.49)
55–59 years	1.41 (0.89 to 2.22)
60–64 years	2.44 (1.41 to 4.22)
≥65 years	1.83 (1.02 to 3.29)
p for subgroup differences	0.31
Socioeconomic status (n = 5 studies)	
Low	1.34 (1.10 to 1.63)
Intermediate	1.14 (0.85 to 1.53)
High	1.27 (0.96 to 1.69)
p for subgroup differences	0.67

industrial sector or formality of the economy, because we did not identify any studies that provided estimates disaggregated by these subgroups.

None of the subgroup analyses showed a statistically significant difference between the subgroups (all p values ≥0.31). Thus, pooled effect estimates did not differ statistically significantly between WHO regions, women and men, different age groups or different SES groups.

Some of the subgroup analyses yielded estimates that appeared to be considerably higher than the estimate from the main analysis. However, such a comparison has to be made with caution for those subgroup analyses that were conducted with selected studies (i.e., sex, age and SES). For example, the subgroup analysis stratified by sex that was based on six studies yielded OR estimates that were higher for both women (1.15, 95% CI: 0.76–1.75) and men (1.21, 95% CI: 1.01–1.44) than the pooled OR estimate from the main analysis (1.08, 95% CI: 0.94–1.24) that was

based on all 17 studies. The forest plots of all subgroup analyses are presented in Appendix 8 in the Supplementary data.

4.5.2. Sensitivity analyses

We conducted two pre-defined sensitivity analyses (Table 7). One sensitivity analysis compared estimates for studies that had assessed depression with the gold standard method (a clinical diagnostic interview; n = 4) versus studies that used other assessment methods (self-administered rating scales or self-reported doctor diagnosed depression; n = 13). The other sensitivity analysis compared estimates for studies with "low"/"probably low" risk of bias in all RoB domains (n = 2) versus studies with at least one rating of "high"/"probably high" in any RoB domain (n = 15).

The two sensitivity analyses did not show a statistically significant effect. That is, estimates were not statistically significantly different for studies that assessed depression with the gold standard method (clinical diagnostic interview), compared with other methods (p = 0.56), nor for studies with only "low"/"probably low" risk of bias ratings compared to studies with one or more "high"/"probably high" risk of bias ratings (p = 0.52). The forest plots of the sensitivity analyses are presented in Appendix 9 in the Supplementary data.

4.6. Quality of evidence

We now report assessments of the quality of evidence for the entire body of evidence on the outcome "Acquired depression" (depression incidence) for the three eligible comparisons included in this systematic review.

4.6.1. Comparison: Worked 41–48 h/week compared with worked 35–40 h/week

We had serious concerns regarding risk of bias in the body of evidence for this comparison. First, we were concerned about risk of selection bias due to incomplete outcome data (domain 6 in our risk of bias assessment), as the majority of studies assessed depression at baseline and then again some years later at follow-up, which means that these studies likely missed cases of depression with onset between baseline and follow-up that were in remission at the time of the follow-up assessment. Second, most studies did not assess whether study participants had ever experienced an episode of depression before assessment at baseline. For these studies, it is unclear whether incident depression during the study period was first time incidence of depression or recurrent incidence of depression. We are uncertain if the incomplete outcome data during follow-up or the failure to assess life-time depression before baseline have biased the estimate of the association between baseline working hours and risk of depression in the studies. But since we cannot rule out risk of bias with confidence, we had serious concerns for risk of bias and consequently downgraded the quality of evidence by one level (−1).

We had no serious concerns for inconsistency, as the I^2 of 46% indicated only moderate heterogeneity (+/−0 levels). We also did not have any serious concerns for indirectness, because the body of evidence reasonably well matched the populations, exposures, comparators and

Table 7
Summary of results from pre-defined sensitivity analyses on long working hours and (≥55 h) and acquiring depression.

Sensitivity analysis	Pooled odds ratio (95% confidence interval)
Depression measurement (n = 17 studies)	
Clinical diagnostic interview	1.28 (0.71 to 2.29)
Other assessment methods	1.07 (0.94 to 1.22)
p for subgroup differences:	0.56
Risk of bias (n = 17 studies)	
Only "low"/"probably low"	1.17 (0.93 to 1.48)
Any "high"/"probably high"	1.07 (0.91 to 1.25)
p for subgroup differences	0.52

outcomes of our interest; we therefore did not downgrade the quality of evidence for this consideration (+/− 0 levels). We had serious concerns for imprecision, because if the lower confidence limit for our best OR estimate (from the meta-analysis) represented the truth (0.86) there would have been an appreciable beneficial effect of exposure to long working hours. If the upper confidence limit represented the truth (OR 1.29), there would have been an appreciable harmful effect of exposure to long working hours. Consequently, we downgraded for imprecision by one level (−1). We did not have any serious concerns for publication bias (+/− 0 levels; funnel plot not calculated because there were fewer than ten studies). There was no large effect estimate, no evidence for a dose–response and no evidence suggesting that residual confounding, bias or effect modification had led to an underestimation of the effect, and consequently we did not upgrade the body of evidence (+/−0 levels). In conclusion, we started at "moderate" quality of evidence for observational studies and downgraded by a total of two levels (−2) and did not upgrade (+/−0) to arrive at a final rating of the quality of evidence as "low"; further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.

4.7. Comparison: Worked 49–54 h/week compared with worked 35–40 h/week

As for weekly working hours of 41–48 (described above), we also had serious concerns regarding risk of bias in the body of evidence on the comparison of weekly working hours 49–54 versus 35–40 for incident depression, because of possible incomplete outcome reporting (domain 6 of the risk of bias assessment) and failure to measure episodes of depression prior to baseline. Consequently, we downgraded the quality of evidence by one level (−1) for risk of bias.

We had no serious concerns for inconsistency, as the I^2 of 40% indicated only moderate heterogeneity (+/−0 levels). We did not have any serious concerns for indirectness because the body of evidence reasonably well matched the populations, exposures, comparators and outcomes of our interest, and we therefore did not downgrade the quality of evidence for this consideration (+/− 0 levels). We however had serious concerns for imprecision, because if the upper confidence limit for our best estimate (from the meta-analysis) represented the truth (OR 1.21), there would have been an appreciable harmful effect of exposure to long working hours, and we therefore downgraded by one level (−1). We did not have serious concerns for publication bias (+/− 0 levels, funnel plot not calculated because there were fewer than ten studies). There was neither a large effect estimate, nor evidence for a dose–response, nor evidence suggesting that residual confounding, bias or effect modification had led to an underestimation of the effect, and consequently we did not upgrade the body of evidence (+/−0 levels). In conclusion, we started at "moderate" quality of evidence for observational studies; downgraded by a total of two levels (−2); did not upgrade (+/−0); and therefore arrived at a final rating of the quality of evidence of: "low".

4.7.1. Comparison: Worked ≥55 h/week compared with worked 35–40 h/week

As for the previous two comparisons (described above), we also had serious concerns regarding risk of bias in the body of evidence on the comparison of weekly working hours of ≥55 compared with 35–40 for incident depression, because of possible incomplete outcome reporting (domain 6 of the risk of bias assessment) and failure to measure episodes of depression prior to baseline. Consequently, we downgraded the quality of evidence by one level (−1) for risk of bias.

We had no serious concerns for inconsistency, as the I^2 of 46% indicated only moderate heterogeneity (+/−0 levels). We did not have any serious concerns for indirectness, because the body of evidence reasonably well matched the populations, exposures, comparators and outcomes of our interest, and we therefore did not downgrade the

quality of evidence for this consideration (+/−0 levels). We had serious concerns for imprecision, because if the upper confidence limit of our best OR estimate (from the meta-analysis) represented the truth (1.24), there would have been an appreciable harmful effect of exposure to long working hours, and we therefore downgraded by one level (−1). We did not have any serious concerns for publication bias, as our funnel plot (Fig. 7) looked reasonably symmetrical and therefore provided no evidence for the presence of publication bias (+/−0 levels). There was no large effect estimate, no evidence for a dose–response and no evidence that residual confounding, biases or effect modification had led to an underestimation of the association; we did not upgrade the quality of evidence (+/−0 levels). In conclusion, we started at "moderate" quality of evidence for observational studies and downgraded by a total of two levels (−2) and did not upgrade (+/−0) to arrive at a final rating of "low" quality of evidence for this comparison.

4.8. Assessment of strength of evidence

According to our protocol, we rated the strength of evidence based on a combination of the four criteria outlined in the Navigation Guide: (1) Quality of the entire body of evidence; (2) Direction of the effect estimate; (3) Confidence in the effect estimate; and (4) Other compelling attributes.

4.8.1. Quality of the entire body of evidence

This systematic review found no studies with evidence on two outcomes: "Has depression" (depression prevalence) and "Died from depression" (depression mortality). For the only outcome with studies included in the systematic review, "Acquired depression" (depression incidence), we judged the quality of the bodies of evidence for all three comparisons to be "low" (see Section 4.6 *Assessment of quality of evidence*). This is the lowest quality of evidence rating within the Navigation Guide framework. Consequently, we consider the quality of evidence for all three included outcomes as insufficient for assessing the strength of evidence for all three outcomes.

4.8.2. Direction of the effect estimate

The bodies of evidence for all three outcomes in all three included comparisons are insufficient to assess the direction of the effects on the outcome of exposure to long working hours. For the only outcome with any included evidence, "Acquired depression", for all three included

comparisons (weekly working hours of 41–48, 49–54 and ≥55, compared with those of 35–40), the CIs of the pooled effect estimates included unity, with the lower limit and the higher limit suggesting moderate to minor decreases and increases, respectively in the odds of the outcome (41–48 h/week: 0.86 to 1.29; 49–54 h/week: 0.93–1.21; ≥55 h/week: 0.94 to 1.24). Thus, it was not possible to conclude whether exposure to long working hours decreased, increased or had no effect on risk of acquiring depression.

4.8.3. Confidence in the effect estimate

Considering that there is no evidence on two included outcomes, "Has depression" and "Died from depression", there are no effect estimates for which we could judge our confidence in them. For the outcome with any included evidence, "Acquired depression", the quality of the body of evidence for all three included comparisons was "low", and the directions of the pooled effect estimates were also unclear for all three included comparisons, as delineated above. Consequently, we have low confidence in the effect estimates for all included comparisons for this outcome.

In addition to this, our confidence in these effect estimates is also low for the following reasons:

- First, no additional data are available on causal pathways explaining the mechanisms that may link exposure to long working hours to depression.
- Second, the assumption of a dose–response relationship between the three exposure categories and the outcome was not supported by our findings.
- Third, even if there was an effect of long working hours on depression, the strength of such a harmful effect would be modest, as even the upper limits of the CI of the pooled effect estimates did not exceed an OR of the size of 1.29. Although even a modest increase in risk can be relevant for policy under conditions of high prevalence of the exposure (which is the case with long working hours, as per (Pega et al., 2021b)), this low level does not increase confidence in the effect estimate.
- Fourth, no intervention studies are available that demonstrate a reduction of the effect estimate because of a reduction of the exposure to a minimal level.
Fig. 7. Funnel plot for acquired depression, worked ≥55 h/week compared with worked 35–40 h/week.

4.8.4. Other compelling attributes

We were not able to access data that could offer evidence for a discussion of other compelling attributes in assessing the strength of evidence. Additional assessment of strength of evidence based on the Bradford Hill considerations (Bradford Hill 1965) is presented in Appendix 9 in the Supplementary data (though note that this is already covered via our approach to evaluating the quality of evidence as described above).

4.8.5. Rating by outcome and comparison

Based on the considerations presented above, we judged the existing bodies of evidence as:

- "Inadequate evidence of harmfulness" for the exposure categories 41–48, 49–54 and ≥ 55h/week for "Has depression" (depression prevalence); the available evidence is insufficient to assess effects of the exposure.
- "Inadequate evidence of harmfulness" for the exposure categories 41–48, 49–54 and ≥55 h/week for "Acquired depression" (depression incidence).
- "Inadequate evidence of harmfulness" for the exposure categories 41–48, 49–54 and ≥55 h/week for the outcome "Died from depression" (depression mortality).

5. Discussion

5.1. Summary of evidence

As shown in the table of summary of findings (Table 8), our systematic review found no eligible study on the outcomes of depression prevalence and depression mortality, resulting in ratings of "low quality of evidence" and "inadequate evidence of harmfulness" for all three exposure categories for these outcomes. Our systematic review found 22 eligible studies for depression incidence, of which 17 studies were included in one or more meta-analyses. We found low quality of evidence and inadequate evidence of harmfulness for the effect of working 41–48, 49–54 and ≥ 55 h/weeks on the outcome of depression incidence, when compared with working 35–40 h/week.

5.2. Comparison to previous systematic review evidence

To our knowledge, three systematic reviews have in recent years examined the association between exposure to long working hours and risk of depression (Theorell et al., 2015; Virtanen et al., 2018; Watanabe et al., 2016). The Theorell et al. (2015) systematic review included six cohort studies and did not conduct a meta-analysis, and the authors concluded that the evidence for any increase of depression from exposure to long working hours was "limited" for women and "very limited" for men. The Watanabe et al. (2016) systematic review included seven cohort studies and reported a modestly elevated pooled RR that included unity (RR 1.24, 95% CI 0.88 to 1.75) for the association between working ≥50 h/week and depression based on a sensitivity analyses of four cohort studies. The Virtanen et al. (2018) systematic review and meta-analysis included 28 studies (ten published and 18 unpublished ones) and reported a RR of 1.14 (95% CI 1.03 to 1.25) for the outcome "depressive symptoms" (combining clinical depression, depressive symptoms and psychological distress) and a RR of 1.09 (95% CI 0.94 to 1.26) for the outcome "depression" (combining clinical depression and depressive symptoms but excluding psychological distress). Our systematic review and meta-analysis covered the three outcomes "Has depression", "Acquired depression" and "Died from depression", identifying 22 studies for the outcome "Acquired depression", while identifying no studies for the outcomes "Has depression" and "Died from depression". Our review included three comparisons (41–48 vs 35–40 h/week, 49–54 vs 35–40 h/week and ≥55 h/week, compared with 35–40 h/week), and it found that the body of evidence for all three outcomes

and all three comparisons was inadequate to assess harmfulness.

Compared to the previous systematic reviews, our systematic review and meta-analysis had some added value. First, we published a protocol detailing all methods of the systematic review and meta-analysis before commencing literature search (Rugulies et al., 2019). Second, by searching seven academic databases and two grey literature databases, our search was more comprehensive than the searches in the previous reviews. Third, we searched the literature up to July 2018 with a supplementary top-up search of Medline shortly before finalizing the article (November 2019) resulting in the most up-to-date review. We considered all studies included in the previous reviews and identified two additional studies (Ahn 2018; Zadow et al., 2019) not included in the previous reviews. Fourth, we were able to re-analyse six studies (Ahn 2018; Kim 2013; NLSY OA Cohort, 2019; Wang et al., 2012a; Wang et al., 2012b; Zadow et al., 2019), allowing us to harmonize exposure data and statistical modelling. Fifth, we applied state-of-the-art methods for assessing quality of evidence and strengths of evidence, using both GRADE (Morgan et al., 2016; Schünemann et al., 2011a) and Navigation Guide methodology (Woodruff and Sutton, 2014).

5.3. Limitations and strengths of this review

5.3.1. Limitations

Our systematic review has several limitations. First, we may have missed eligible studies, for example due to them being published in languages other than English. However, as we searched seven academic and two grey literature databases using a comprehensive search strategy, conducted an extensive hand search and consulted additional experts who also did not identify any additional eligible studies, we believe it is unlikely that we missed any important study.

Second, we did not receive a substantial amount of the missing data we requested for the studies included in this systematic review. We requested missing data from principal study authors at least three times, but the principal study authors generally did not share these requested missing data with us or only shared selected data. As a result, subgroup analyses by sex, age group and SES could only be conducted for a limited number of studies.

Third, all identified eligible studies were observational studies and therefore vulnerable to bias due to unmeasured confounding. Experimental studies, quasi-experimental studies or natural experiments could have provided stronger evidence, but we did not find any of these study types that fulfilled our inclusion criteria. We found one remarkable uncontrolled before-and-after study with first-year medical residents in Japan that measured depressive symptoms and clinical depression before and after entering residency (Ogawa et al., 2018). Entering residency led to exposure to very long working hours, with 45% of residents reporting working ≥ 80 h/week. The study showed a marked increase of depressive symptoms in the study participants after 3 months in residency, particularly amongst residents working 80–99 h/week and ≥100 h/week, suggesting that very long working hours, exceeding the predefined working hours categories in our review, might substantially increase risk of depression. However, as the study was conducted without a control group, it did not fulfil our predefined eligibility criteria, and we had to exclude it from our systematic review.

Fourth, the validity of exposure assessment was somehow restricted, not only due to concerns of self-reported exposure measurements, but also since exposure to long working hours was assessed at baseline only. This has likely resulted in exposure misclassification, as average hours worked per week may change over time. Further, the lack of repeated measures of exposure made it impossible to analyse the potential effect of changes in exposure.

Fifth, we provided subgroup analyses stratified by WHO region, but national health, labour and other social policies, as well as welfare state regimes, may vary considerably within these regions. It is conceivable that these variations modify association between working conditions, including exposure to long working hours, and risk of depression

Table 8
Summary of findings.

Effect of exposure to long working hours on depression among workers

Population: all workers of working age (≥15 years)
Settings: all countries and work settings
Exposure: worked 41–48, 49–54 or ≥55 h/week
Comparator: worked 35–40 h/ week

Outcomes	Exposure category	Illustrative comparative risks (95% CI)		Relative effect (95% CI)	No. of participants (studies)	Navigation Guide (Woodruff and Sutton 2014) quality of evidence rating	Navigation Guide strength of evidence rating for human evidence	Comments
		Assumed risk Unexposed workers (worked 35–40 h/week)	Corresponding risk Workers in the exposure category					
Has depression	–	–	–	–	–	–	Inadequate evidence of harmfulness	No evidence was found on this outcome.
Acquired depression (measured with clinical diagnostic interview, validated self-administered rating scales or self-reported doctor-diagnosed or treated depression) Follow-up: 1–10 years	Worked 41–48 h/ week	349 cases per 10,000 person-years	366 cases per 10,000 person-years (300 to 450)	OR 1.05 (0.86 to 1.29)	49,392 (8 studies)	⊕⊖⊖ Low [b]	Inadequate evidence of harmfulness	Better indicated by lower values. Additional evidence from four studies not included in the meta-analysis also provided no evidence for an effect of this comparison on the outcome. We are very uncertain about the effect of this exposure category on this outcome.
	Worked 49–54 h/ week		370 cases per 10,000 person-years (325 to 422)	OR 1.06 (0.93 to 1.21)	49,392 (8 studies)	⊕⊖⊖ Low [b]	Inadequate evidence of harmfulness	Better indicated by lower values. Additional evidence from four studies not included in the meta-analysis also provided no evidence for an effect of this comparison on the outcome. We are very uncertain about the effect of this exposure category on this outcome.
	Worked ≥55 h/ week		377 cases per 10,000 person-years (328 to 433)	OR 1.08 (0.94 to 1.24)	91,142 (17 studies)	⊕⊖⊖ Low [b]	Inadequate evidence of harmfulness	Better indicated by lower values. Additional evidence from five studies not included in the meta-analysis also provided no evidence for an effect of this comparison on the outcome. We are very uncertain about the effect of this exposure category on this outcome.
Died from depression	–	–	–	–	–	–	Inadequate evidence of harmfulness	No evidence was found on this outcome.

CI: confidence interval; **OR**: odds ratio.
Navigation Guide quality of evidence ratings:
  High quality: Further research is very unlikely to change our confidence in the estimate of effect.
  Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
  Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
Navigation Guide strength of evidence ratings
  Sufficient evidence of harmfulness: The available evidence usually includes consistent results from well-designed, well-conducted studies, and the conclusion is unlikely to be strongly affected by the results of future studies. For human evidence a positive relationship is observed between exposure and outcome where chance, bias, and confounding, can be ruled out with reasonable confidence.
  Limited evidence of harmfulness: The available evidence is sufficient to determine the effects of the exposure, but confidence in the estimate is constrained by such factors as: the number, size, or quality of individual studies, the confidence in the effect, or inconsistency of findings across individual studies. As more information becomes available, the observed effect could change, and this change may be large enough to alter the conclusion. For human evidence a positive relationship is observed between exposure and outcome where chance, bias, and confounding cannot be ruled out with reasonable confidence.
  Inadequate evidence of harmfulness: Studies permit no conclusion about a toxic effect. The available evidence is insufficient to assess effects of the exposure. Evidence is insufficient because of: the limited number or size of studies, low quality of individual studies, or inconsistency of findings across individual studies. More information may allow an estimation of effects.
  Evidence of lack of harmfulness: The available evidence includes consistent results from well-designed, well-conducted studies, and the conclusion is unlikely to be strongly affected by the results of future studies. For human evidence more than one study showed no effect on the outcome of interest at the full range of exposure levels that humans are known to encounter, where bias and confounding can be ruled out with reasonable confidence. The conclusion is limited to the age at exposure and/or other conditions and levels of exposure studied.

Footnotes:
[a] As assumed risk we extracted the risk in the study by Wang et al. (2012a) because this study was rated with "low"/"probably low" risk of bias in all domains and further used the gold standard measure, a clinical diagnostic interview, to measure incident depression
[b] Downgraded by two levels (−2) in total, comprising downgrading by one level each for serious concerns for risk of bias (−1) and imprecision (−1).

(Dragano et al., 2011; Lunau et al., 2013), yet our data did not allow us to examine such a possible effect modification.

Sixth, the subgroup analyses by sex, age and SES could not been performed with all studies, but only with a subsample of those studies that provided estimates stratified by these variables. We cannot rule out that subgroup analyses would have provided different results, had we been able to conduct them with all included studies.

Seventh, as in all systematic reviews, we included studies that were conducted in the past. Work environment conditions, including working time arrangements, from the time period of the studies that we included in the review might be different from current or future work environment conditions, and changes might sometimes occur rapidly and to a dramatic extent, for example in the global financial crisis that emerged in 2007 (Torá et al., 2015) or in the current COVID-19 pandemic (Burdorf et al., 2020; Sim, 2020). Whether this would affect the applicability of the results of this systematic review needs to be investigated in future studies.

5.3.2. Strengths

Our systematic review and meta-analysis have several strengths, including:

- Strictly speaking, previous systematic reviews have not undergone all steps of a systematic review (see Fig. 1 in (Woodruff and Sutton, 2014)), but our systematic review and meta-analysis have done so, including having pre-published a protocol (Rugulies et al., 2019) and having assessed the strength of evidence; this presents a substantial improvement in systematic review methods on the topic.
- Previous systematic reviews have not commonly and not comprehensively provided detailed analyses across all analytic steps of the systematic review and meta-analysis for comparisons of standard categories of exposure to long working hours compared with standard working hours, but we have provided such analyses for three such comparisons commonly used in the epidemiological literature across all steps of the systematic review, and again this provides an improvement in accuracy of systematic review evidence on this topic.
- Whereas previous systematic review evidence has not commonly and comprehensively assessed risk of bias and quality of evidence using established systematic review frameworks with dedicated tools and approaches, we have applied the Navigation Guide framework in this systematic review, which should have ensured rigor and transparency in this systematic review.
- In previous systematic reviews, strength of the evidence was not commonly assessed, but in our systematic review we have applied pre-specified criteria to rate the strength of evidence for each included comparison for each included outcome; again, this is a novel contribution to the systematic review and meta-analytic body of evidence on the topic.
- Finally, to our knowledge, this is amongst the first systematic reviews and meta-analyses conducted specifically for a global occupational burden of disease study, and as such it provides a model for future systematic reviews that will help ensure that these global health estimates adhere fully with the *GATHER Guidelines for Accurate and Transparent Health Estimates Reporting* (Stevens et al., 2016).

6. Use of evidence for burden of disease estimation

This systematic review and meta-analysis was conducted by WHO and ILO, supported by a large number of individual experts, for the development of the WHO/ILO Joint Estimates ((Pega et al., 2021a) Ryder, 2017). More specifically, it provides the evidence base for the organizations to consider producing estimates of the burden of deaths and DALYs from depression attributable to exposure to long working hours. The systematic review found a considerable number of studies, but the body of evidence was rated as "inadequate evidence of

harmfulness" of exposure to long working hours for having, acquiring and dying from depression; the available evidence is insufficient to assess effects of the exposure. Producing estimates of the burden of depression attributable to exposure to long working hours appears therefore not evidence-based at this point.

To improve the evidence base for WHO and ILO's future considerations of producing WHO/ILO Joint Estimates of the depression burden from exposure to long working hours, better studies are needed that examine whether and to what extent working long hours increases risk of depression. Such studies should address the limitations in the literature identified in this systematic review, including:

- Assessing depression not only at baseline and follow-up, but also continuously monitoring the onset of depression between baseline and follow-up, which would allow to conduct time-to-event analyses. This can be done for example by using register data for hospital-treated depression, as has been shown in research on the association between job strain and clinical depression (Madsen et al., 2017).
- Assessing lifetime prevalence of depression prior to baseline, to distinguish between first-time onset of depression and onset of recurrent depression during follow-up. This can be done either by diagnostic interviews (Wang et al., 2012a) or by use of health register data (Svane-Petersen et al., 2020).
- Measuring exposure to long working hours not only once but repeatedly, taking changes in exposure into consideration. This would not only give more precise exposure data but also allow analysing observational data as a non-randomized pseudo trial; this has been done for example in research on onset of impaired sleep and change in health-related behaviours (Clark et al., 2015).
- Conducting experiments (if found to be ethical and feasible) and quasi-experimental studies, including natural experiment studies, on the effect of exposure to long working hours on the risk of depression.

7. Conclusions

We did not identify studies providing evidence on the association between long working hours and depression prevalence and depression mortality. Regarding depression incidence, we identified 22 studies. From these bodies of evidence, we are very uncertain regarding the effect of exposure to long working hours on having, acquiring and dying from depression and judged the existing bodies of evidence from human data as "inadequate evidence for harmfulness" for the exposure categories 41–48, 48–54 and ≥55 h/week, compared with 35–40 h/week.

8. Differences between protocol and systematic review

- In the protocol, we planned to convert ORs into RRs, if possible. For such conversions, information on the "prevalence of outcome in reference group or baseline risk" is required. However, such information was not available from the included studies. As all included studies reported ORs, we meta-analysed these ORs.
- There were no deviations from the Medline search strategy that was published in the protocol other than corrections of typing errors (e. g., missing parentheses).

Sponsors

The sponsors of this systematic review are the World Health Organization (WHO) and the International Labour Organization (ILO).

Author contributions

Had the idea for this systematic review: FP, Ivan Ivanov (WHO), Nancy Leppink (ILO).

Selected the lead reviewers and gathered the review teams: FP, Ivan Ivanov, Nancy Leppink.

Coordinated the entire series of systematic reviews: FP, YU.

Was the lead reviewer of this systematic review: RR.

Led the design of the systematic review, including developed the standard methods: FP.

Contributed substantially to the design of the systematic review: RR, KS, CDT, MB, BMR, YU, ED, JLA-M, MC, AD, ND, JL, QD-M, HE, JG, LG, IEHM, DVP, GS, JS, KT, AZ, SI.

Conducted additional analyses of original data: KS, SA, LG, JK, JW, AZ.

Conducted the search: RR, KS, CDT, MB, BMR.

Selected studies: RR, KS, CDT, MB, BMR, ED, JLA-M, MC, ND, QD-M, HE, JG, IEHM, GS, KT AZ, SI.

Extracted data: KS, CDT, MB, BMR.

Requested missing data: RR.

Assessed risk of bias: RR, KS, CDT, MB, BMR, SI.

Conducted the meta-analyses: RR, KS, FP.

Assessed quality of evidence: RR, KS.

Assessed strength of evidence: RR, KS.

Developed the standards and wrote the template for all systematic reviews in the series: FP.

Wrote the first draft of the manuscript using the template: RR, KS.

Revised the manuscript critically for important intellectual content: All authors.

Ensured tailoring of the systematic review for WHO/ILO estimation purposes: FP.

Ensured harmonization across systematic reviews in the series: FP.

Approved the final version of the systematic review to be published: All authors.

Agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved: All authors.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

Long working hours and depressive symptoms: systematic review and meta-analysis of published studies and unpublished individual participant data

by Virtanen M, Jokela M, Madsen IEH, Magnusson Hanson LL, Lallukka T, Nyberg ST, Alfredsson L, Batty GD, Bjorner JB, Borritz M, Burr H, Dragano N, Erbel R, Ferrie JE, Heikkilä K, Knutsson A, Koskenvuo M, Lahelma E, Nielsen ML, Oksanen T, Pejtersen JH, Pentti J, Rahkonen O, Rugulies R, Salo P, Schupp J, Shipley MJ, Siegrist J, Singh-Manoux A, Suominen SB, Theorell T, Vahtera J, Wagner GG, Wang JL, Yiengprugsawan V, Westerlund H, Kivimäki M

This study was the first large-scale meta-analysis of prospective studies on long working hours and the onset of depression, including both published data and unpublished individual participant data (189 729 participants from Europe, Asia, North America and Australia). The findings suggested an increased risk of depression linked to prior overtime work in Europe and, to an even higher extent, in Asia.

Long working hours and depressive symptoms: systematic review and meta-analysis of published studies and unpublished individual participant data

by Marianna Virtanen, PhD,[1, 2] Markus Jokela, PhD,[3] Ida EH Madsen, PhD,[4] Linda L Magnusson Hanson, PhD,[5] Tea Lallukka, PhD,[1, 6] Solja T Nyberg, PhD,[6] Lars Alfredsson, PhD,[7, 8] G David Batty, DSc,[9] Jakob B Bjorner, MD, PhD,[4] Marianne Borritz, PhD,[10] Hermann Burr, PhD,[11] Nico Dragano, PhD,[12] Raimund Erbel, MD, PhD,[13] Jane E Ferrie, PhD,[9, 14] Katriina Heikkilä, PhD,[15] Anders Knutsson, PhD,[16] Markku Koskenvuo, MD, PhD,[6] Eero Lahelma, PhD,[6] Martin L Nielsen, PhD,[17] Tuula Oksanen, PhD,[1] Jan H Pejtersen, PhD,[18] Jaana Pentti, PhD,[6] Ossi Rahkonen, PhD,[6] Reiner Rugulies, PhD,[4, 19] Paula Salo, PhD,[1, 20] Jürgen Schupp, PhD,[21, 22] Martin J Shipley, PhD[9] Johannes Siegrist, PhD,[12] Archana Singh-Manoux, PhD,[9, 23] Sakari B Suominen, PhD,[24, 25, 26] Töres Theorell, MD, PhD,[5] Jussi Vahtera, MD, PhD,[24, 27] Gert G Wagner, PhD,[21, 28, 29] Jian Li Wang, PhD,[30] Vasoontara Yiengprugsawan, PhD,[31] Hugo Westerlund, PhD,[5] Mika Kivimäki, PhD [1, 6, 9]

Objectives   This systematic review and meta-analysis combined published study-level data and unpublished individual-participant data with the aim of quantifying the relation between long working hours and the onset of depressive symptoms.

Methods   We searched PubMed and Embase for published prospective cohort studies and included available cohorts with unpublished individual-participant data. We used a random-effects meta-analysis to calculate summary estimates across studies.

Results   We identified ten published cohort studies and included unpublished individual-participant data from 18 studies. In the majority of cohorts, long working hours was defined as working $\geq$55 hours per week. In multivariable-adjusted meta-analyses of 189 729 participants from 35 countries [96 275 men, 93 454 women, follow-up ranging from 1–5 years, 21 747 new-onset cases), there was an overall association of 1.14 (95% confidence interval (CI) 1.03–1.25] between long working hours and the onset of depressive symptoms, with significant evidence of heterogeneity (I^2=45.1%, P=0.004). A strong association between working hours and depressive symptoms was found in Asian countries (1.50, 95% CI 1.13–2.01), a weaker association in Europe (1.11, 95% CI 1.00–1.22), and no association in North America (0.97, 95% CI 0.70–1.34) or Australia (0.95, 95% CI 0.70–1.29). Differences by other characteristics were small.

Conclusions   This observational evidence suggests a moderate association between long working hours and onset of depressive symptoms in Asia and a small association in Europe.

Key terms   depression; mental health; overtime; psychological distress; working life; working time.

Depression is a leading cause of years lived with disability, contributing to a significant proportion of disease burden worldwide (1). Given that the burden of mental disorders peaks at working age (1), working-age populations are an important target for prevention. There is growing evidence to suggest a link between work characteristics and the onset of depression, with perceived psychosocial work stress being the most often investigated work exposure (2–7).

Recently, studies have also focused on long working hours as a potential risk factor for mental disorders (8). However, although several reviews of this field exist (5, 9–24), the few systematic quantifications of the evidence have been based on published cross-sectional (18, 19, 25) or published longitudinal studies (26). Given the potential publication bias in studies based on published data (27), an individual-participant meta-analysis of unpublished data would provide important complementary evidence to evaluate the effect of long working hours on mental health. Furthermore, long working hours are more common in Asia and North America than in Europe and the risk of mental health problems is higher among women and individuals with low socioeconomic position than men and those with high socioeconomic status. As determinants and mechanisms that harm and protect mental health may also vary by region and sociodemographic factors, research should examine whether there are systematic differences in the association between long working hours and mental health between countries and employee groups. These issues have not been addressed in previous reviews on long working hours and mental health.

With large prospective data including cohort studies with both published and unpublished data, this review is the first large-scale study of the association between long working hours and onset of depressive symptoms.

Methods

Search strategy and selection criteria

Following the PRISMA guidelines (28), we carried out systematic searches of the PubMed and Embase databases, taking into account publications up to January 2017, using the following search terms without restrictions: ("work hours", "working hours", "overtime") and ("mental health", "mental disorders", "psychological distress", "depressive symptoms", "depression"). We also examined the reference lists of reviews in the field as well as those of the eligible publications, and performed a cited-reference search of these using Institute of Scientific Information Web of Science (to January 2017). Two authors independently reviewed titles and abstracts of the articles and, for selected publications, carried out fulltext review against inclusion criteria.

The following eligibility criteria were applied to published studies: at least results (eg, abstract, tables) published in English; prospective cohort design with individual level exposure and outcome data with follow-up of 1–5 years; the effect of long working hours examined using shorter hours as a reference group; outcome being onset of depressive disorder, depressive symptoms, depressive disorder, or psychological distress; and results reporting either as relative risk (RR), odds

ratios (OR), or hazard ratios (HR) with 95% confidence intervals (CI), or sufficient information provided to calculate these estimates.

We extracted the following information from each eligible study: name of the first author; year of study entry (publication year if not reported); study site (country); population; number of participants; proportion of women; mean age or age range at baseline; mean follow-up time; measure of depressive symptoms; number and proportion (of study population) of new cases; covariates included in the multivariable models; and the effect estimate for the association between long working hours and depressive symptoms.

Unpublished individual participant data

The second part of the study included unpublished individual-level data from studies included in the Individual-Participant-Data Meta-analysis in Working Populations (IPD-Work) Consortium, which has previously published several meta-analyses on other outcomes (29, 30), or were open access at one of two potential sources: the Inter-University Consortium for Political and Social Research (ICPSR; www.icpsr.umich.edu/icpsrweb/ICPSR) or the UK Data Service (ukdataservice.ac.uk). Each study has existing approval from their relevant local or national ethics committee, and all participants had given informed consent.

Quality assessment

Two authors assessed study quality using Cochrane's "Tool to Assess Risk of Bias in Cohort Studies" in the following domains: (i) Can we be confident in the assessment of exposure (ie, the predictor variables)? (ii) Were the exposed and non-exposed cohorts selected from the same population? (iii) Can we be confident that the outcome of interest was not present at the start of the study? (iv) Did the statistical analysis adjust for the confounding variables? (v) Can we be confident in the assessment of the presence or absence of confounding factors? (vi) Can we be confident in the assessment of the outcome? (vii) Was the follow-up of the cohorts adequate?

The studies were evaluated in relation to each question using a four-level scale: "definitely yes"," probably/mostly yes", "probably/mostly no", and "definitely no". The quality of the study was considered high/acceptable if all domains were evaluated favorably, ie, "definitely yes" or "probably/mostly yes" (see details in supplementary table A, www.sjweh.fi/show_abstract.php?abstract_id=3712).

Statistical analysis

We used a two-stage meta-analysis (31) in which study-specific estimates were obtained from published studies and studies with individual participant data at the first stage. In all studies, the baseline cases were excluded in order to allow assessment of onset of depressive symptoms to be examined. With an expectation of heterogeneity between studies, we used random-effects meta-analysis in the second stage to obtain a pooled estimate from the first stage study-specific analyses. We used OR as an estimator of effect and their 95% CI as an indicator of precision, comparing long working hours (most often defined as ≥55 weekly hours) with standard hours (most often 35–40 hours). In cohort studies with individual participant data, the OR were adjusted for age, sex, socioeconomic status, and marital status. For published studies, we used models that were closest to that set of adjustments. Heterogeneity of the estimates was first assessed using the I^2 statistic. Heterogeneity test and meta-regression were used to assess subgroup differences. Subgroup analyses included sex (men versus women), age group (<50 years versus ≥50 years), socioeconomic status (high, intermediate, low), geographic region (Europe, Asia, North America, Australia), publication status (published versus unpublished), study baseline year (1991–99 versus 2000–10), study population (population based versus occupational cohort), study quality (low versus high/acceptable), length of follow-up (1–2 versus 3–5 years), response rate at baseline (≤65 versus >65%), loss to follow-up (≤25 versus >25%), outcome type (psychological distress versus depressive symptoms), population prevalence of symptoms at baseline (<15 versus ≥15%), and population onset of symptoms at follow-up (<15 versus ≥15%). We tested for publication bias in published studies by using the funnel plot of the estimates against their standard errors and Egger's test for small-study effects (32). We used SAS 9.4 (SAS Institute, Cary, NC, USA) and Stata 13.1 (StataCorp, College Station, TX, USA) to analyze study-specific data and Stata 13.1 for meta-analyses.

Results

Literature search results

By January 2017, we identified 3295 studies from Embase and 1740 studies from PubMed (supplementary figure A, www.sjweh.fi/show_abstract.php?abstract_id=3712). After screening the abstracts, full text review was performed for 170 articles. Of these, six studies met the inclusion criteria and a further four were identified from referred publication searches, hand search, and from the reference lists of published reviews. We excluded meta-analyses (but extracted relevant studies from those) (18, 19, 25, 26), reviews (5, 8–17, 21, 23), and books (20,

22, 24). We also excluded studies with overlapping data with selected studies (33–40), those without adjustment for baseline mental health (41–43), and those prospective studies in which exposure and outcome were temporally overlapping (44, 45). However, we performed a descriptive, qualitative analysis of studies which included prospective analysis with continuous outcomes rather than outcomes indicating onset of illness (46, 47), a study with exposure treated as a continuous variable (48), longitudinal within-subject design with continuous outcomes (49), and broader mental health outcomes, such as antidepressant use (50, 51), all treated mental disorders (52), or disability claims due to all mental disorders (53). Results of these studies are presented in supplementary table B, www.sjweh.fi/show_abstract.php?abstract_id=3712. None of these studies suggested an association between working hours and mental health.

Descriptive statistics for the identified eligible ten published studies (54–63) are presented in supplementary table C, www.sjweh.fi/show_abstract.php?abstract_id=3712. The range of study entry year varied between 1992–2010. Four studies were from Japan (54, 58, 59, 62), two from Canada (56, 61), and one each from the UK (57), Sweden (55), France (60), and South Korea (63). In three studies, there were separate estimates for men and women (54–56). Adjustment for covariates varied between none (58), stratification by sex (54, 55), and multivariable (56, 57, 59–63).

Unpublished individual participant data

A total of 18 studies (64–81) from the IPD-Work Consortium, open access databases and the Thai Cohort Study (TCS) (80) via personal communication provided unpublished individual-level data for working hours and onset of depressive symptoms (supplementary table C). The study baseline year ranged from 1986–2009. Four studies were from the UK (65, 69, 73, 81), three from the US (64, 66, 67), three from Finland (68, 71, 74), two from Denmark (70, 72), two from Germany (77, 79), and one each from Australia (76), Thailand (80), and Sweden (78). A total of 25 European countries and Israel participated in the Survey of Health, Ageing and Retirement in Europe (SHARE) (75), including France, Germany, Finland, Sweden, Denmark, Slovenia, Cyprus, Romania, Bulgaria, Greece, Czech Republic, Slovakia, Hungary, Estonia, Latvia, Lithuania, Poland, The Netherlands, Belgium, Luxembourg, Spain, Portugal, Italy, Switzerland, and Austria.

In total, the number of participants in published studies and individual participant data was 189 729 (96 275 men, 93 454 women) from 35 countries. The number of cases with new-onset depressive symptoms was 21 747 (the average onset 11.5%).

Assessment of long working hours

With previous evidence suggesting that working ≥ 55 hours per week may be harmful for health (29, 30) and with the European Union Directive recommending a limit of 48 hours per week (82) in the present analyses of studies with individual-level data, we used the following categories of hours worked per week: <35, 35–40 (reference group), 41–48, 49–54 and ≥ 55 hours. This categorization was used in all unpublished datasets and via personal communication for a published study by Wang et al (61). In the Helsinki Health Study (HHS) (74), study members had responded to an enquiry about time worked using a pre-defined categorization (<30, 30–40, 41–50 and >50 hours per week) which, for the purposes of the present analyses, we used 30–40 hours per week (reference group) with >50 working hours as the highest group. In the published studies, there was variation in how long working hours were defined in the analyses: >12 versus ≤ 8 hours /day (54); ≥ 41 hours /week versus less (56); >48 hours a week versus less (60); >60 versus ≤ 50 hours /week (62); 60 or more hours versus less (59); >55/week versus 35–40 (57); >68 hours versus 35–40 (63); ≥ 40 hours overtime /month versus less (58); and "often working overtime" versus not (55). To evaluate whether this heterogeneity in exposure assessment had an effect on results, we conducted separate analyses for published studies and unpublished individual participant data, in addition to overall pooled estimates.

Ascertainment of depressive symptoms

Most of the studies assessed self-reported depressive symptoms or psychological distress using survey questionnaires. Structured interview-based methods based on Diagnostic and Statistical Manual of Mental Disorders (DSM-III) or DSM-IV diagnostic criteria were used in three published studies (56, 60, 61) to assess major depressive disorder or major depressive episode (see supplementary table C).

Assessment of individual- and study-level characteristics

The published studies had used different covariate adjustments (supplementary table C). In cohort studies with the individual participant data, we extracted the following: age, sex, marital status (married/cohabited versus not) and socioeconomic status (SES) which, based on register or survey-based occupational position, or educational qualification, was categorized as high, intermediate, or low. Other factors included geographic region (Europe, Asia, North America, Australia), publication status (published versus unpublished), study baseline year (1991–99 versus 2000–10), study population (population based versus occupational cohort), study

quality (low versus high/acceptable), length of follow-up (1–2 versus 3–5 years), response rate at baseline (≤65 versus >65%), loss to follow-up (≤25 versus >25%), outcome type (psychological distress versus depressive symptoms), population prevalence of symptoms at baseline (<15 versus ≥15%), and population onset of symptoms at follow-up (<15 versus ≥15%).

Quality assessment

Results from the study quality assessment are presented in supplementary table A. The scores ranged between 7–11 out of the best possible 14 points; the best (11 points) in the present analysis being assigned to the studies by Shields (56) and Niedhammer et al (60). Of the 28 studies, all but three (54, 55, 58) were considered being of high /acceptable quality, that is, having no components with serious threat of bias. The three studies lost score points due to lack of confounder adjustments and inadequate exposure. To examine potential other sources of bias not assessed in the tool, we included in the subgroup analyses publication status, study baseline year, type of population, response rate at baseline, loss to follow-up, outcome type, prevalence of depressive symptoms in the study population at baseline and proportion of those with new-onset of symptoms at follow-up (see also supplementary table D, www.sjweh.fi/show_abstract.php?abstract_id=3712).

Long working hours and onset of depressive symptoms

Study-specific association between long working hours and onset of depressive symptoms is presented in figure 1. The overall OR was 1.14 (95% CI 1.03–1.25) after multivariable adjustments. The I^2 statistics (I^2=45.1%, P=0.004) suggested significant heterogeneity between the studies

A significant difference was found for Asia versus other geographic regions (*P*=0.034 using heterogeneity test; P=0.041 using meta-regression). Also in figure 1, study-specific forest plots by geographic region are shown for the association between long working hours and depressive symptoms. The OR was 1.50 (95% CI 1.13–2.01) for Asia, 1.11 (95% CI 1.004–1.22) for Europe, 0.97 (95% CI 0.70–1.34) for North America, and 0.95 (95% CI 0.70–1.29) for the one study representing Australia. However, significant heterogeneity was still present in subgroups of studies from Asia and North America although all Asian studies suggested a positive association between long working hours and depressive symptoms.

Results from other subgroup analyses are displayed in figure 2. There were two characteristics with evidence of subgroup differences; published versus unpublished data (P-values 0.075 and 0.018 using heterogeneity test

and meta-regression, respectively), and population-based versus occupational cohort (P-values 0.048 and 0.092). Published studies indicated a 1.35-fold (95% CI 1.07–1.71) risk of depressive symptoms whereas unpublished data suggested a 1.08-fold (95% CI 1.00–1.16) increased risk. The estimate for occupational cohorts was 1.34 (95% CI 1.10–1.62) and for population-based studies 1.07 (95% CI 0.96–1.20). Meta-regression P-values for other estimates (not shown in the figure) were as follows: study baseline year P=0.458; study quality P=0.440; length of follow-up P=0.958; response rate P=0.805; loss to follow-up P=0.720; outcome type P=0.415; population prevalence of symptoms at baseline P=0.880; population onset of symptoms P=0.308. Furthermore, no significant subgroup differences were found when the outcome type was categorized into three groups: "psychological distress", "depressive symptoms", and "clinical depression" (P=0.619 and 0.588 in heterogeneity test and meta-regression, respectively). The Egger test of publication bias did not show evidence for publication bias neither among the ten published estimates nor among the subgroup of Asian-origin studies. The OR for the association between long working hours and depressive symptoms was 1.65 (95% CI 1.30–2.09) in published studies from Asia whereas it was 1.07 (95% CI 0.74–1.55) in other published studies (P for difference=0.053). Thus, a stronger association in Asia than in other countries was found both in all studies and within published studies.

Discussion

In this systematic review and meta-analysis of nearly 190 000 participants from 28 prospective cohort studies in 35 countries, the overall association between long working hours and depressive symptoms was 1.14-fold (95% CI 1.03–1.25), with significant heterogeneity between studies. The subgroup analyses revealed that the summary estimate appeared to vary by geographic region; whereby the pooled estimates suggested no association between long working hours and depressive symptoms in the studies from North America and Australia and a small association in the studies from Europe, it was larger (OR 1.50, 95% CI 1.13–2.01) in the studies conducted in Asian countries.

Of the three previous meta-analyses of the association between long working hours and mental health, two were published in 1997 (18) and 2008 (19), and were mainly based on cross-sectional data. They reported a weak linear correlation between hours worked and "mental strain", which is consistent with our findings. A more recent meta-analysis identified seven published prospective studies and a summary estimate which

Figure 1. Random-effects meta-analysis of the association between long working hours and the onset of depressive symptoms by geographic region. OR, odds ratio.

indicated an increased (RR=1.08) but statistically non-significant risk of clinical depressive disorder associated with long working hours (26). However, all previous meta-analyses were exclusively based on published data and their ability to examine subgroup differences was limited.

In our meta-analysis, the association between long working hours and depressive symptoms was stronger in Asian countries, including studies from Japan, South Korea and Thailand, than the rest of the countries from Europe, North America, and Australia. The reasons for this regional difference are unclear, but they might involve cultural and occupational health policy differences between Asian and Western societies. According to the effort–reward imbalance model (83), health risks of long working hours are smaller if efforts at work (long hours) are rewarded by economic rewards, promotion, esteem, and high job security. In the ideal scenario, working long hours is voluntary and leads to increased

rewards; the unfavorable scenario involves involuntary long working hours combined with low rewards (84). Another theoretical framework, the effort–recovery model (85) posits that long working hours may reduce the time for recovery to an extent that increases the risk of fatigue and associated mental health symptoms. In the present meta-analysis, however, we were not able to determine whether effort–reward or effort–recovery imbalance mediate the association between long working hours and depressive symptoms. However, a study from South-Korea showed that low job security, a component of low rewards, predicted depressive symptoms, suicidal ideation and impaired self-rated health (86). In addition, in Japan, sense of community is a fundamental feature of the society, and an important endeavor in individuals is to be in harmony with the community – including working community – rather than achieving one's individualistic goals (87). The Asian work culture, described as "worker bees", may lead to a prolonged

Figure 2. Subgroup analyses for the association between long working hours and the onset of depressive symptoms. [OR=odds ratio.] [a] P-value for difference between groups.

struggling with overwhelming workload without seeing any other options (88). Suicide (Karojisatsu) caused by overwork has been suggested to be common because showing weakness, such as depression, in work spheres means betraying one's co-workers (87). Other issues in Asian countries might relate to limited prevention and treatment of depression and social stigma related to mental disorders, which might restrain help-seeking at an early phase of the disease (88).

In addition to geographic region, an effect modifier was found for publication status and cohort type. The estimate suggested a stronger association in published studies than unpublished studies although the funnel plot test suggested sources other than small study publication bias underlay this difference. The association was also stronger in studies that were based on occupational cohorts than in those derived from the general population. However, as there was only one study from Asia in the unpublished group and one in the population-based

group, further meta-analyses with a greater number of Asian studies are needed to determine whether these other subgroup differences underlay the geographic difference in the association between long working hours and depressive symptoms.

The studies included in this meta-analysis have some important limitations. Exposure to working hours was based on self-reports in all studies and measured only once. Self-report may involve recall bias due to the participants' inability to recall hours worked accurately. However, the validity of self-reported working hours has been found to be moderate or good (89, 90). A non-systematic error in the assessment of working hours is likely to attenuate the association between long working hours and depressive symptoms and recall bias may artificially inflate the observed associations only if the error in the number of hours worked is systematically correlating with mental health status. Furthermore, with exposure measured at one time point only, we were not

able to assess whether the relatively small overall risk found in this meta-analysis was an underestimate due to misclassification of the exposure, ie, that for some employees, excessive working hours was a temporary work situation as their working hours declined during the follow-up whereas for some others working hours could have increased. Unlike unpublished individual-level data, the definition of exposure to working hours also varied among published studies.

There was also variation in how depressive symptoms were assessed. Some of the studies used more general outcomes of psychological distress while other studies used more specific measures of depressive symptoms or clinical depressive disorder. However, the association was similar across these three outcome measures. In only three studies (56, 60, 61), structured interview-based methods for DSM-III or DSM-IV diagnostic criteria for depressive disorder was used, thus the majority of studies in this meta-analysis concerned depressive symptoms or psychological distress. However, sub-clinical depression has been shown to be a more important indicator of health than previously thought (91) although the association found in our study was not dependent on the outcome type.

Furthermore, bias due to unmeasured confounding cannot be ruled out in observational studies, which can of course only provide insights into association, not causality. For example, unmeasured work-related (such as low job control, job strain and shift work) and behavioral factors (such as alcohol consumption) might have contributed to the association between long working hours and depressive symptoms. However, previous studies show that long working hours are associated with high job demands and high control ("active job") rather than high strain jobs (high demands with low control) (92, 93), making low job control and job strain unlikely confounders. Similarly, there is no strong longitudinal evidence linking shift work to depression (94), and long working hours has been found to be only modestly associated with risky alcohol use (30). In combination, unmeasured confounders should be associated both with long working hours and depressive symptoms with an odds ratio of 1.54 (95% CI 1.21–1.81) to entirely explain the present findings (95). However, one more limitation of the present study is that the vast majority of studies were based on populations from high-income countries; therefore the findings are not generalizable to low- or middle-income countries.

Concluding remarks

In this meta-analysis of prospective studies with up to 190 000 employees from 35 countries, long working hours, typically defined as ≥55 weekly working hours, were associated with a modest 1.14-fold increased risk of new-onset depressive symptoms, with high level of heterogeneity between studies, but also evidence that this association may be context-specific. Accordingly, the odds of having depressive symptoms at follow-up was 1.5-fold in individuals working long hours in Asian countries while the corresponding OR was 1.1 in Europe and less than that in North America and Australia. Further research is needed to determine the specific reasons behind these differences and to develop policies to prevent depression due to excessive working hours.
